# GLOSSARY OF TERMS

## Guide to Reading and Understanding Your Laboratory Report

The information below is designed to better explain the various terms used in your report of analytical results from the Laboratory. This is not intended as a comprehensive explanation, and if you have additional questions please contact your project representative.

Results Disclaimer - Information that may be provided by the customer, and contained within this report, include Permit Limits, Project Name, Sample ID, Sample Matrix, Sample Preservation, Field Blanks, Field Spikes, Field Duplicates, On-Site Data, Sampling Collection Dates/Times, and Sampling Location. Results relate to the accuracy of this information provided, and as the samples are received.

## Abbreviations and Definitions

| | |
|---|---|
| MDL | Method Detection Limit. |
| ND | Not detected at the Reporting Limit (or MDL where applicable). |
| RDL | Reported Detection Limit. |
| Rec. | Recovery. |
| RPD | Relative Percent Difference. |
| SDG | Sample Delivery Group. |
| (S) | Surrogate (Surrogate Standard) - Analytes added to every blank, sample, Laboratory Control Sample/Duplicate and Matrix Spike/Duplicate; used to evaluate analytical efficiency by measuring recovery. Surrogates are not expected to be detected in all environmental media. |
| U | Not detected at the Reporting Limit (or MDL where applicable). |
| Analyte | The name of the particular compound or analysis performed. Some Analyses and Methods will have multiple analytes reported. |
| Dilution | If the sample matrix contains an interfering material, the sample preparation volume or weight values differ from the standard, or if concentrations of analytes in the sample are higher than the highest limit of concentration that the laboratory can accurately report, the sample may be diluted for analysis. If a value different than 1 is used in this field, the result reported has already been corrected for this factor. |
| Limits | These are the target % recovery ranges or % difference value that the laboratory has historically determined as normal for the method and analyte being reported. Successful QC Sample analysis will target all analytes recovered or duplicated within these ranges. |
| Original Sample | The non-spiked sample in the prep batch used to determine the Relative Percent Difference (RPD) from a quality control sample. The Original Sample may not be included within the reported SDG. |
| Qualifier | This column provides a letter and/or number designation that corresponds to additional information concerning the result reported. If a Qualifier is present, a definition per Qualifier is provided within the Glossary and Definitions page and potentially a discussion of possible implications of the Qualifier in the Case Narrative if applicable. |
| Result | The actual analytical final result (corrected for any sample specific characteristics) reported for your sample. If there was no measurable result returned for a specific analyte, the result in this column may state “ND” (Not Detected) or “BDL” (Below Detectable Levels). The information in the results column should always be accompanied by either an MDL (Method Detection Limit) or RDL (Reporting Detection Limit) that defines the lowest value that the laboratory could detect or report for this analyte. |
| Uncertainty (Radiochemistry) | Confidence level of 2 sigma. |
| Case Narrative (Cn) | A brief discussion about the included sample results, including a discussion of any non-conformances to protocol observed either at sample receipt by the laboratory from the field or during the analytical process. If present, there will be a section in the Case Narrative to discuss the meaning of any data qualifiers used in the report. |
| Quality Control Summary (Qc) | This section of the report includes the results of the laboratory quality control analyses required by procedure or analytical methods to assist in evaluating the validity of the results reported for your samples. These analyses are not being performed on your samples typically, but on laboratory generated material. |
| Sample Chain of Custody (Sc) | This is the document created in the field when your samples were initially collected. This is used to verify the time and date of collection, the person collecting the samples, and the analyses that the laboratory is requested to perform. This chain of custody also documents all persons (excluding commercial shippers) that have had control or possession of the samples from the time of collection until delivery to the laboratory for analysis. |
| Sample Results (Sr) | This section of your report will provide the results of all testing performed on your samples. These results are provided by sample ID and are separated by the analyses performed on each sample. The header line of each analysis section for each sample will provide the name and method number for the analysis reported. |
| Sample Summary (Ss) | This section of the Analytical Report defines the specific analyses performed for each sample ID, including the dates and times of preparation and/or analysis. |

| Qualifier | Description |
|---|---|
| J1 | Surrogate recovery limits have been exceeded; values are outside upper control limits. |
| J3 | The associated batch QC was outside the established quality control range for precision. |
| J5 | The sample matrix interfered with the ability to make any accurate determination; spike value is high. |
| J6 | The sample matrix interfered with the ability to make any accurate determination; spike value is low. |

# CASE NARRATIVE

All sample aliquots were received at the correct temperature, in the proper containers, with the appropriate preservatives, and within method specified holding times, unless qualified or notated within the report. Where applicable, all MDL (LOD) and RDL (LOQ) values reported for environmental samples have been corrected for the dilution factor used in the analysis. All Method and Batch Quality Control are within established criteria except where addressed in this case narrative, a non-conformance form or properly qualified within the sample results. By my digital signature below, I affirm to the best of my knowledge, all problems/anomalies observed by the laboratory as having the potential to affect the quality of the data have been identified by the laboratory, and no information or data have been knowingly withheld that would affect the quality of the data.

Tony Gibson
Project Manager

## Report Revision History

Level II Report - Version 1: 10/25/23 16:01

## Project Narrative

Updated sample id for sample -10 - Tony Gibson 10/31/23

## Volatile Organic Compounds (GC) by Method 8015D/GRO

| Analyte | Result mg/l | Qualifier | RDL mg/l | Dilution | Analysis date / time | Batch |
|---|---|---|---|---|---|---|
| TPH (GC/FID) Low Fraction | ND | | 0.100 | 1 | 10/19/2023 12:26 | WG2154045 |

# GLOSSARY OF TERMS

## Guide to Reading and Understanding Your Laboratory Report

The information below is designed to better explain the various terms used in your report of analytical results from the Laboratory. This is not intended as a comprehensive explanation, and if you have additional questions please contact your project representative.

Results Disclaimer - Information that may be provided by the customer, and contained within this report, include Permit Limits, Project Name, Sample ID, Sample Matrix, Sample Preservation, Field Blanks, Field Spikes, Field Duplicates, On-Site Data, Sampling Collection Dates/Times, and Sampling Location. Results relate to the accuracy of this information provided, and as the samples are received.

## Abbreviations and Definitions

| | |
|---|---|
| MDL | Method Detection Limit. |
| ND | Not detected at the Reporting Limit (or MDL where applicable). |
| RDL | Reported Detection Limit. |
| Rec. | Recovery. |
| RPD | Relative Percent Difference. |
| SDG | Sample Delivery Group. |
| (S) | Surrogate (Surrogate Standard) - Analytes added to every blank, sample, Laboratory Control Sample/Duplicate and Matrix Spike/Duplicate; used to evaluate analytical efficiency by measuring recovery. Surrogates are not expected to be detected in all environmental media. |
| U | Not detected at the Reporting Limit (or MDL where applicable). |
| Analyte | The name of the particular compound or analysis performed. Some Analyses and Methods will have multiple analytes reported. |
| Dilution | If the sample matrix contains an interfering material, the sample preparation volume or weight values differ from the standard, or if concentrations of analytes in the sample are higher than the highest limit of concentration that the laboratory can accurately report, the sample may be diluted for analysis. If a value different than 1 is used in this field, the result reported has already been corrected for this factor. |
| Limits | These are the target % recovery ranges or % difference value that the laboratory has historically determined as normal for the method and analyte being reported. Successful QC Sample analysis will target all analytes recovered or duplicated within these ranges. |
| Qualifier | This column provides a letter and/or number designation that corresponds to additional information concerning the result reported. If a Qualifier is present, a definition per Qualifier is provided within the Glossary and Definitions page and potentially a discussion of possible implications of the Qualifier in the Case Narrative if applicable. |
| Result | The actual analytical final result (corrected for any sample specific characteristics) reported for your sample. If there was no measurable result returned for a specific analyte, the result in this column may state “ND” (Not Detected) or “BDL” (Below Detectable Levels). The information in the results column should always be accompanied by either an MDL (Method Detection Limit) or RDL (Reporting Detection Limit) that defines the lowest value that the laboratory could detect or report for this analyte. |
| Uncertainty (Radiochemistry) | Confidence level of 2 sigma. |
| Case Narrative (Cn) | A brief discussion about the included sample results, including a discussion of any non-conformances to protocol observed either at sample receipt by the laboratory from the field or during the analytical process. If present, there will be a section in the Case Narrative to discuss the meaning of any data qualifiers used in the report. |
| Quality Control Summary (Qc) | This section of the report includes the results of the laboratory quality control analyses required by procedure or analytical methods to assist in evaluating the validity of the results reported for your samples. These analyses are not being performed on your samples typically, but on laboratory generated material. |
| Sample Chain of Custody (Sc) | This is the document created in the field when your samples were initially collected. This is used to verify the time and date of collection, the person collecting the samples, and the analyses that the laboratory is requested to perform. This chain of custody also documents all persons (excluding commercial shippers) that have had control or possession of the samples from the time of collection until delivery to the laboratory for analysis. |
| Sample Results (Sr) | This section of your report will provide the results of all testing performed on your samples. These results are provided by sample ID and are separated by the analyses performed on each sample. The header line of each analysis section for each sample will provide the name and method number for the analysis reported. |
| Sample Summary (Ss) | This section of the Analytical Report defines the specific analyses performed for each sample ID, including the dates and times of preparation and/or analysis. |

| Qualifier | Description |
|---|---|
| B | The same analyte is found in the associated blank. |
| J | The identification of the analyte is acceptable; the reported value is an estimate. |
| J1 | Surrogate recovery limits have been exceeded; values are outside upper control limits. |
| J2 | Surrogate recovery limits have been exceeded; values are outside lower control limits. |
| J7 | Surrogate recovery cannot be used for control limit evaluation due to dilution. |

# CASE NARRATIVE

All sample aliquots were received at the correct temperature, in the proper containers, with the appropriate preservatives, and within method specified holding times, unless qualified or notated within the report. Where applicable, all MDL (LOD) and RDL (LOQ) values reported for environmental samples have been corrected for the dilution factor used in the analysis. All Method and Batch Quality Control are within established criteria except where addressed in this case narrative, a non-conformance form or properly qualified within the sample results. By my digital signature below, I affirm to the best of my knowledge, all problems/anomalies observed by the laboratory as having the potential to affect the quality of the data have been identified by the laboratory, and no information or data have been knowingly withheld that would affect the quality of the data.

John Hawkins
Project Manager

## Volatile Organic Compounds (GC) by Method 8015D/GRO

# GLOSSARY OF TERMS

## Guide to Reading and Understanding Your Laboratory Report

The information below is designed to better explain the various terms used in your report of analytical results from the Laboratory. This is not intended as a comprehensive explanation, and if you have additional questions please contact your project representative.

Results Disclaimer - Information that may be provided by the customer, and contained within this report, include Permit Limits, Project Name, Sample ID, Sample Matrix, Sample Preservation, Field Blanks, Field Spikes, Field Duplicates, On-Site Data, Sampling Collection Dates/Times, and Sampling Location. Results relate to the accuracy of this information provided, and as the samples are received.

## Abbreviations and Definitions

| | |
|---|---|
| MDL | Method Detection Limit. |
| ND | Not detected at the Reporting Limit (or MDL where applicable). |
| RDL | Reported Detection Limit. |
| Rec. | Recovery. |
| RPD | Relative Percent Difference. |
| SDG | Sample Delivery Group. |
| (S) | Surrogate (Surrogate Standard) - Analytes added to every blank, sample, Laboratory Control Sample/Duplicate and Matrix Spike/Duplicate; used to evaluate analytical efficiency by measuring recovery. Surrogates are not expected to be detected in all environmental media. |
| U | Not detected at the Reporting Limit (or MDL where applicable). |
| Analyte | The name of the particular compound or analysis performed. Some Analyses and Methods will have multiple analytes reported. |
| Dilution | If the sample matrix contains an interfering material, the sample preparation volume or weight values differ from the standard, or if concentrations of analytes in the sample are higher than the highest limit of concentration that the laboratory can accurately report, the sample may be diluted for analysis. If a value different than 1 is used in this field, the result reported has already been corrected for this factor. |
| Limits | These are the target % recovery ranges or % difference value that the laboratory has historically determined as normal for the method and analyte being reported. Successful QC Sample analysis will target all analytes recovered or duplicated within these ranges. |
| Qualifier | This column provides a letter and/or number designation that corresponds to additional information concerning the result reported. If a Qualifier is present, a definition per Qualifier is provided within the Glossary and Definitions page and potentially a discussion of possible implications of the Qualifier in the Case Narrative if applicable. |
| Result | The actual analytical final result (corrected for any sample specific characteristics) reported for your sample. If there was no measurable result returned for a specific analyte, the result in this column may state “ND” (Not Detected) or “BDL” (Below Detectable Levels). The information in the results column should always be accompanied by either an MDL (Method Detection Limit) or RDL (Reporting Detection Limit) that defines the lowest value that the laboratory could detect or report for this analyte. |
| Uncertainty (Radiochemistry) | Confidence level of 2 sigma. |
| Case Narrative (Cn) | A brief discussion about the included sample results, including a discussion of any non-conformances to protocol observed either at sample receipt by the laboratory from the field or during the analytical process. If present, there will be a section in the Case Narrative to discuss the meaning of any data qualifiers used in the report. |
| Quality Control Summary (Qc) | This section of the report includes the results of the laboratory quality control analyses required by procedure or analytical methods to assist in evaluating the validity of the results reported for your samples. These analyses are not being performed on your samples typically, but on laboratory generated material. |
| Sample Chain of Custody (Sc) | This is the document created in the field when your samples were initially collected. This is used to verify the time and date of collection, the person collecting the samples, and the analyses that the laboratory is requested to perform. This chain of custody also documents all persons (excluding commercial shippers) that have had control or possession of the samples from the time of collection until delivery to the laboratory for analysis. |
| Sample Results (Sr) | This section of your report will provide the results of all testing performed on your samples. These results are provided by sample ID and are separated by the analyses performed on each sample. The header line of each analysis section for each sample will provide the name and method number for the analysis reported. |
| Sample Summary (Ss) | This section of the Analytical Report defines the specific analyses performed for each sample ID, including the dates and times of preparation and/or analysis. |

| Qualifier | Description |
|---|---|
| J1 | Surrogate recovery limits have been exceeded; values are outside upper control limits. |
| J2 | Surrogate recovery limits have been exceeded; values are outside lower control limits. |

# CASE NARRATIVE

All sample aliquots were received at the correct temperature, in the proper containers, with the appropriate preservatives, and within method specified holding times, unless qualified or notated within the report. Where applicable, all MDL (LOD) and RDL (LOQ) values reported for environmental samples have been corrected for the dilution factor used in the analysis. All Method and Batch Quality Control are within established criteria except where addressed in this case narrative, a non-conformance form or properly qualified within the sample results. By my digital signature below, I affirm to the best of my knowledge, all problems/anomalies observed by the laboratory as having the potential to affect the quality of the data have been identified by the laboratory, and no information or data have been knowingly withheld that would affect the quality of the data.

John Hawkins
Project Manager

## Volatile Organic Compounds (GC) by Method 8015D/GRO

| Analyte | Result mg/l | Qualifier | RDL mg/l | Dilution | Analysis date / time | Batch |

# GLOSSARY OF TERMS

## Guide to Reading and Understanding Your Laboratory Report

The information below is designed to better explain the various terms used in your report of analytical results from the Laboratory. This is not intended as a comprehensive explanation, and if you have additional questions please contact your project representative.

Results Disclaimer - Information that may be provided by the customer, and contained within this report, include Permit Limits, Project Name, Sample ID, Sample Matrix, Sample Preservation, Field Blanks, Field Spikes, Field Duplicates, On-Site Data, Sampling Collection Dates/Times, and Sampling Location. Results relate to the accuracy of this information provided, and as the samples are received.

## Abbreviations and Definitions

| | |
|---|---|
| MDL | Method Detection Limit. |
| ND | Not detected at the Reporting Limit (or MDL where applicable). |
| RDL | Reported Detection Limit. |
| Rec. | Recovery. |
| RPD | Relative Percent Difference. |
| SDG | Sample Delivery Group. |
| (S) | Surrogate (Surrogate Standard) - Analytes added to every blank, sample, Laboratory Control Sample/Duplicate and Matrix Spike/Duplicate; used to evaluate analytical efficiency by measuring recovery. Surrogates are not expected to be detected in all environmental media. |
| U | Not detected at the Reporting Limit (or MDL where applicable). |
| Analyte | The name of the particular compound or analysis performed. Some Analyses and Methods will have multiple analytes reported. |
| Dilution | If the sample matrix contains an interfering material, the sample preparation volume or weight values differ from the standard, or if concentrations of analytes in the sample are higher than the highest limit of concentration that the laboratory can accurately report, the sample may be diluted for analysis. If a value different than 1 is used in this field, the result reported has already been corrected for this factor. |
| Limits | These are the target % recovery ranges or % difference value that the laboratory has historically determined as normal for the method and analyte being reported. Successful QC Sample analysis will target all analytes recovered or duplicated within these ranges. |
| Original Sample | The non-spiked sample in the prep batch used to determine the Relative Percent Difference (RPD) from a quality control sample. The Original Sample may not be included within the reported SDG. |
| Qualifier | This column provides a letter and/or number designation that corresponds to additional information concerning the result reported. If a Qualifier is present, a definition per Qualifier is provided within the Glossary and Definitions page and potentially a discussion of possible implications of the Qualifier in the Case Narrative if applicable. |
| Result | The actual analytical final result (corrected for any sample specific characteristics) reported for your sample. If there was no measurable result returned for a specific analyte, the result in this column may state “ND” (Not Detected) or “BDL” (Below Detectable Levels). The information in the results column should always be accompanied by either an MDL (Method Detection Limit) or RDL (Reporting Detection Limit) that defines the lowest value that the laboratory could detect or report for this analyte. |
| Uncertainty (Radiochemistry) | Confidence level of 2 sigma. |
| Case Narrative (Cn) | A brief discussion about the included sample results, including a discussion of any non-conformances to protocol observed either at sample receipt by the laboratory from the field or during the analytical process. If present, there will be a section in the Case Narrative to discuss the meaning of any data qualifiers used in the report. |
| Quality Control Summary (Qc) | This section of the report includes the results of the laboratory quality control analyses required by procedure or analytical methods to assist in evaluating the validity of the results reported for your samples. These analyses are not being performed on your samples typically, but on laboratory generated material. |
| Sample Chain of Custody (Sc) | This is the document created in the field when your samples were initially collected. This is used to verify the time and date of collection, the person collecting the samples, and the analyses that the laboratory is requested to perform. This chain of custody also documents all persons (excluding commercial shippers) that have had control or possession of the samples from the time of collection until delivery to the laboratory for analysis. |
| Sample Results (Sr) | This section of your report will provide the results of all testing performed on your samples. These results are provided by sample ID and are separated by the analyses performed on each sample. The header line of each analysis section for each sample will provide the name and method number for the analysis reported. |
| Sample Summary (Ss) | This section of the Analytical Report defines the specific analyses performed for each sample ID, including the dates and times of preparation and/or analysis. |

| Qualifier | Description |
|---|---|
| J | The identification of the analyte is acceptable; the reported value is an estimate. |
| J1 | Surrogate recovery limits have been exceeded; values are outside upper control limits. |
| J3 | The associated batch QC was outside the established quality control range for precision. |

# 1.0 INTRODUCTION

This report presents a comprehensive, regulator-ready engineering plan for the expansion of the permanent disposal cell at the Mt. Taylor Uranium Mine facility, located in Cibola County, New Mexico. The primary objective of this reclamation undertaking is to ensure the safe, efficient, and centralized containment of waste streams generated during historic mining operations, extended standby periods, and recent closure activities. These waste streams include legacy radioactive materials, radiologically contaminated soils, and localized volumes of non-hazardous diesel-impacted soils that require permanent engineered isolation. The proposed expansion is designed to comply with applicable state and federal regulations and to provide long-term protection of human health and the surrounding environment. The key regulatory frameworks governing this design include standards issued by the U.S. Nuclear Regulatory Commission (NRC), the U.S. Environmental Protection Agency (EPA), and the New Mexico Environment Department (NMED).

The technical foundation for this disposal cell expansion centers on an optimized, multi-layered engineered cover system designed to perform effectively in a semi-arid climate. The cover system relies on locally sourced clay borrow materials, as characterized during the January 2025 field investigation, to form a low-permeability radon barrier, overlain by protective soil and erosion-resistant rock mulch layers. This revision (Rev 1) incorporates three supplemental technical analyses completed subsequent to the original report: (1) a cover optimization memorandum evaluating reduction of overall cover thickness through revised frost depth estimation, elimination of the capillary layer, and radon sensitivity analysis; (2) a regulatory evaluation of co-placement of diesel-impacted and radiologically elevated soils within the expanded cell; and (3) a statistical comparison of 2018–2025 on-site climate data to historical and regional design-support datasets confirming the continued validity of design-basis climate inputs. These analyses are fully integrated into the relevant sections of this report.

Earthwork and grading activities will reshape the site to optimize drainage, limit water infiltration, and establish a stable base for the expanded disposal cell. Erosion control strategies embedded within the expansion plan include rock mulch facing, stormwater diversion channels, and controlled surface grades to reduce runoff concentration. The design considers the site's stratigraphy and draws on recent geotechnical data to confirm the appropriateness of selected construction materials, containment approaches, and long-term performance assumptions.

Engineering Analytics, Inc. (EA) prepared this report for Rio Grande Resources (RGR) to integrate site characterization, regulatory requirements, recent field and laboratory findings, and supplemental technical evaluations into a cohesive engineering basis for the proposed disposal cell expansion. The following sections present supporting analyses, modeling results, design criteria, and implementation recommendations needed to guide agency review, permitting, construction planning, quality assurance, sequencing decisions, construction documentation, and execution of the reclamation work.

# 2.0 CURRENT SITE CONDITIONS

## 2.1 Location and Land Use

The Mt. Taylor uranium mine is located approximately 25 miles northeast of Grants, New Mexico, in Cibola County. The mine was initially developed by Gulf Mineral Resources (Gulf) in 1971. Figure 2-1 shows the site location plan. Following surface drilling, several ore bodies were identified across a span of over seven miles, with estimated reserves totaling 120 million pounds of uranium oxide (Alief and Kern, 1989). Two shafts, measuring 24 feet and 14 feet in diameter, were constructed to access ore deposits located 3,100 to 3,200 feet beneath the surface within the Westwater Canyon Member of the Morrison Formation. Figure 2-2 shows the detailed site plan. In the 1970s, wells were installed to extract groundwater for mining operations.

Mining activities commenced in 1980 but ceased in September 1982 due to unfavorable market conditions. Ownership transferred to Chevron Resources Company following a merger with Gulf in 1985, leading to the resumption of mining from 1986 to 1990 using standard underground room-and-pillar techniques. During this period, approximately 675,000 tons of uranium ore and about 698,000 tons of waste rock were extracted.

In 1991, Rio Grande Resources Corporation (RGR) acquired the site but did not resume mining operations owing to unfavorable market conditions. Beginning in 2019, RGR initiated mine closure and land reclamation efforts under the oversight of NMED and the Energy, Minerals, and Natural Resources Department. Prior to closure, surface infrastructure at the site included two shafts, an ore stockpile, a waste rock pile, stormwater retention ponds, a sewage treatment plant, an ion exchange facility, eight clay-lined treatment ponds, and various ancillary support structures.

## 2.2 Geology

The geologic setting of the mine has been described in detail in the Baseline Study prepared by New Mexico Environmental Institute (NMEI) in 1974 (NMEI, 1974) and the Site Assessment submitted in 1994 (RGR, 1994a). Deposits of Quaternary age rock and soil exposed in the area consist of unconsolidated talus, alluvial, and eolian sediments. Extensive areas on the slopes adjacent to the high basalt-covered mesas to the south, southwest, and east of the mine are covered by talus, landslides, and black lava blocks. Beneath the valleys and lower topographic slopes, clay, silt, sand, and gravel alluvial lenses are present (NMEI, 1974).

The deepest geologic formation encountered in the Mount Taylor mine shaft is the Jurassic-age Morrison Formation. This formation consists, in ascending order, of the Recapture Creek, Westwater Canyon, and Brushy Basin members. The Recapture Creek member occurs at a depth between 3,240 and 3,300 feet below ground surface (ft bgs) in the mine shaft pilot well. This member grades vertically into the overlying Westwater Canyon member. The transition to the Westwater Canyon member marks a change in lithology, and its thickness varies due to lensing and vertical gradations into both the Brushy Basin and Recapture Creek members. At the mine site, the Westwater Canyon member is divided into Upper and Lower units by a persistent shale layer. The lower sandstone unit is 60 to 70 feet thick, while the upper sandstone unit measures about 100 feet thick in the mine shaft area. These sandstone units contain most of the uranium ore

reserves of mine. Above the Westwater Canyon member, the Brushy Basin member conformably overlies and interfingers with it. The Brushy Basin is approximately 80 feet thick and consists of shales and claystones at the mine shaft.

Above the ore-bearing Morrison Formation is a sequence of sedimentary units approximately 2,950 feet thick. The first of these is the Dakota Sandstone, which unconformably overlies the Brushy Basin member. The Dakota Sandstone is 50 to 60 feet thick and is only slightly mineralized, thus not mined at Mt. Taylor Mine. The Dakota Sandstone conformably intertongues with the overlying Mancos Shale.

Next in the stratigraphic sequence is the Mancos Shale, which is 900 feet thick and composed chiefly of dark-gray, calcareous, marine clay shale. This unit also contains interspersed sandstone beds. The lowermost portion of the Mancos Shale includes three sandstone units known as the Upper, Middle, and Lower Tres Hermanos Sandstones, which are 72 feet, 45 feet, and 118 feet thick, respectively, at the mine shaft pilot well (McGlothin, 1972).

Continuing upward, the Mancos Shale extends to the base of the Gallup Sandstone at approximately 2,050 feet bgs. The Gallup Sandstone consists of two separate sandstone units divided by 130 feet of dark gray shale. Overlying the Gallup Sandstone is the Crevasse Canyon Formation, which includes, in ascending order, the Dilco Coal, the Stray Sand, the Mulatto Tongue of the Mancos Shale, the Dalton Sandstone, and the Gibson Coal. The Point Lookout Formation conformably overlies the Crevasse Canyon Formation.

Above the Crevasse Canyon Formation lies the Point Lookout Formation, which is the basal unit of the Mesa Verde Group. This formation is typically encountered between 700 and 850 feet bgs at the mine site. Near the mine, it is separated into two units by the Satan Tongue of the Mancos Shale. The upper unit, referred to as the Point Lookout Sandstone, is the main body and is typically 110 to 130 feet thick. The lower unit is the Lower Hosta Tongue, a transgressive marine beach sandstone that is between 80 and 100 feet thick. Along the southern margin of the basin, both units merge into a combined unit approximately 250 feet thick. The Lower Hosta Tongue is of limited areal extent, pinching out 30 miles northeast of its outcrop. The Point Lookout Sandstone comprises thick- to very thick-bedded, very fine- to medium-grained, locally cross-bedded sandstones. Notably, the Point Lookout aquifer provides the domestic water supply for both the mine and the Village of San Mateo.

The uppermost geological unit present at the mine is the Menefee Formation. It forms uneven slopes around the mine and near the Village of San Mateo. The Menefee Formation is composed of interbedded pale yellowish-brown siltstone, fine to medium-grained sandstone, gray shale, carbonaceous shale, and thin coal beds. Its thickness in the mine shaft is approximately 767 feet (NMEI, 1974). Mine water treatment pond basins were excavated into the Menefee Formation, and both the manway/vent and production shafts are collared in this unit.

The stratigraphic complexity at the site affects groundwater flow, material properties, and mine closure planning. Aquifers like the Point Lookout Sandstone supply water to the area and are separated from deeper systems by low-permeability units such as Crevasse Canyon and Mancos

Shale, which function as natural barriers against contamination. The Menefee Formation, containing various sediments and coal beds, impacts surface facility stability and provides material for disposal cell expansion, with its clay-rich layers important for cover design to limit infiltration and erosion.

Accurate geological profiling is vital for selecting construction materials, designing effective waste containment strategies, and ensuring regulatory compliance. Upcoming sections will detail recent field studies and lab tests that further inform expansion plans.

## 2.3 Results of January 2025 Field Investigation

Engineering Analytics excavated 24 test pits and collected samples from three proposed borrow sites to assess clay material for disposal cell cover. In January 2025, EA used a CAT backhoe to excavate the pits (A-1 to A-6, B-1 to B-5, and C-1 to C-13), each to a depth of approximately 6 feet. Figure 2-3 shows the test pit locations. The test pit logs are provided in Appendix A. Subsurface conditions included:

**Topsoil:**
The topsoil thicknesses at the site range from 2 inches to 6 inches. The topsoil consists of organics, loose sand, and is very dry.

**Sand:**
The topsoil is underlain by a sand layer at all the test pit locations except at locations A-6, B-1, B-2, C-2, and C-8. Silty sand underlies the topsoil at location A-6, sand and gravel at location B-1, and clay at location B-2. Sandy clay lies beneath the topsoil at C-2 and C-8 test-pit locations. The sand layer is loose to very loose, frozen at some locations, dry to moist, and fine in texture. The termination depths of the sand layer range from 3 feet to the excavation depth of 6 feet.

**Sand and Gravel:**
Sand and gravel layer underlies the topsoil at test pit location B-1. This layer is loose, dry, and non-plastic. This layer extends to a depth of three feet at the test pit location. This layer is only encountered in test-pit location B-1.

**Silty Sand:**
At test pit location A-6, a silty sand layer underlies the topsoil and extends to a depth of 4 feet. This layer is moist, loose, and very fine in texture.

**Clay:**
A thin layer of clay underlies the topsoil at test pit location B-2. The clay is stiff, low plastic, and moist. The clay layer extends to a depth of one foot and is found frozen during the investigation.

**Sandy Clay:**
Sandy clay is present at most test pit sites, except A-3, A-6, B-2, B-3, B-5, and C-12. This material is stiff to very stiff, dry, and lies below the sand layer at depths of 3 to 4 feet, extending to 6 feet. At C-13, there is no sand layer, and at C-4, sandy clay ends at 5 feet underlain by sand. The absence of sandy clay at A-3, A-6, B-2, B-3, B-5, and C-12 may be due to limited excavation depth.

**Siltstone:**
Siltstone is present beneath the silty sand layer at test pit location A-6. The siltstone is dry, fine, and contains silt fragments. The siltstone extends from a depth of 4 feet to the termination depth of the excavation at 6 feet.

## 2.4 Results of Laboratory Testing for the Site

### 2.4.1 *Historical Laboratory Testing*

Engineering Analytics personnel conducted a review of previous laboratory testing associated with the site and supplemented these efforts with additional laboratory analyses to support the disposal cell expansion design. Both the historical data and the tests performed by EA in 2025 formed the basis for the analysis undertaken for the disposal cell expansion design.

### 2.4.2 *Laboratory Testing Completed in 2025*

Selected material samples from Borrow Sources A, B, and C (see Figure 2.3) underwent laboratory testing to determine their physical and geotechnical properties for the disposal cell expansion design. Tests included water content, Atterberg limits, standard Proctor compaction, soil water characteristics, and consolidated undrained triaxial tests. EA performed and summarized these tests below. Test-pit logs and laboratory reports are provided in Appendices A and Appendix B, respectively.

**Water Content:** Measurements of water content and dry density were conducted on selected samples in accordance with ASTM test methods D2216 and D2937, respectively. The water content of the tested samples ranged from 4.6% to 24.1%. For the clay, silty clay, and sandy clay samples, the moisture content ranged from 6.8% to 24.1%, with an average of 11.7%, and a mode of 9.7%.

**Atterberg Limits:** Atterberg limits were determined for selected samples in accordance with ASTM test method D4318. These measurements facilitate the classification of soil. Based on the Unified Soil Classification System (USCS), a total of 48 samples were analyzed: nine were identified as non-plastic (NP), 29 as low plasticity clay (CL), two as high plasticity clay (CH), three as low plasticity silt (ML), and five as low plasticity clay or silt (CL-ML).

**Standard Proctor Compaction Tests:** Eight Standard Proctor Compaction Tests were conducted following ASTM test method D698. For the clay, silty clay, and sandy clay samples, maximum dry density ranged from 89.8 to 110.4 pcf, with optimum moisture content (OMC) varying between 16.1% and 26.6%. Sand soil specimens exhibited maximum dry densities from 111.1 to 117.6 pcf, with corresponding OMC values ranging from 12.2% to 15%.

**Consolidated Undrained (CU) Triaxial Tests:** EA performed two CU triaxial tests with pore pressure measurements per ASTM D4767 at its certified lab. This method assesses strength and stress-strain properties of saturated cohesive soil specimens by isotropic consolidation followed by undrained axial compression at a constant strain rate, allowing calculation of total and effective stresses from measured axial load, deformation, and pore-water pressure. The tests results on

remolded clay samples showed an average effective friction angle of 31° with zero effective cohesion.

## 2.5 Seismicity

EA conducted a seismic hazard analysis for RGR pertaining to the Mt. Taylor Uranium Mine. The objective was to determine peak horizontal ground acceleration (PGA) for stability assessments, specifically focusing on a 10,000-year return period. The site is located within the Colorado Plateau, which exhibits structural stability, though it is proximate to tectonically active regions including the Rio Grande Rift and the Jemez Lineament. The historical record, spanning 1568 to 2025, indicates low seismic activity, with only a few moderate events occurring near the site. The largest recorded earthquake had a magnitude of 5.9 and was situated approximately 160 km away, while the nearest significant event (Mw 4.08) occurred 13 km from the facility.

Both deterministic and probabilistic analyses were performed. The deterministic approach identified a maximum PGA of 0.09g from a hypothetical Maximum Credible Earthquake (MCE 6.3) located 15.1 km from the site. The probabilistic analysis calculated a mean PGA of 0.21g for the 10,000-year return period. Based on this value, a pseudostatic seismic coefficient equal to two-thirds of the PGA (0.14g) was applied in seismic evaluations of the disposal cell. The seismic hazard at Mt. Taylor Mine is assessed as relatively low, with background seismicity representing the primary risk. Appendix C presents the results of the seismic hazard analysis.

## 2.6 Climate

The Mt. Taylor Mine is located on the southwestern slope of Mount Taylor in the San Mateo area of west-central New Mexico at an elevation of approximately 7,400 feet above mean sea level. The site lies within the Colorado Plateau and experiences a cold semi-arid climate characterized by low humidity, high solar radiation, large daily temperature swings, and a pronounced July to September monsoon. These conditions support an evapotranspiration-based cover design because annual atmospheric moisture demand substantially exceeds precipitation.

Continuous meteorological data have been collected at the San Mateo on-site station (elevation ~7,400 ft) since October 2017. EA compared the 2018 to 2025 on-site record to two long-term regional datasets: (1) the Gallup Municipal Airport climate normal (elevation ~6,500 ft, ~45 miles northwest of the mine), which represents the long-term semi-arid regional rainfall regime, and (2) the Rice Park SNOTEL station (elevation ~8,900 ft, ~20 miles northeast of the mine), which represents high-elevation winter hydrology including snow water equivalent (SWE), snowmelt timing, and freeze-thaw behavior. The stations differ in elevation, climate regime, and hydrologic processes, which explains the differing mean annual precipitation (MAP) values: 11.65 inches at Gallup, 10.02 inches at San Mateo, and approximately 6.5 inches at Rice Park, where snowpack sublimation and wind redistribution reduce measured precipitation. Despite these differences, statistical testing (Appendix F) showed no significant departures ($p > 0.05$) in precipitation, temperature, or air freezing index (AFI) between the San Mateo record and the broader historical population, confirming that the site data fall within normal regional variability.

Because the on-site San Mateo meteorological data is both site-specific and statistically consistent with long-term regional conditions, it is used as the primary dataset for the water balance, infiltration, and Copper Rule analyses. Its daily resolution record captures the monsoon-driven wetting season, recent warming trends, and the actual hydrologic inputs influencing the cover today, while remaining conservative relative to Gallup's higher long-term MAP. Gallup provides the stable 30-year precipitation benchmark needed to anchor the short site record and prevent anomalous wet or dry bias in design assumptions. Rice Park, although drier, supplies long-term winter hydrology, particularly SWE, snowmelt infiltration pulses, and freeze-thaw behavior that on-site San Mateo has not measured. For this reason, the AFI used in design is based on Rice Park projections and historical distributions, ensuring a conservative frost penetration estimate. The design-basis AFI of 927.5 degree-days (200-year return period) exceeds the historical maximum by approximately 18 percent, confirming that frost-related cover thickness and radon-barrier protection remain conservatively defined.

Mean annual precipitation at the site is approximately 10 inches, while estimated potential evapotranspiration is 26.45 inches, producing an annual moisture deficit of 16.44 inches and an aridity index of 0.38. Monthly (potential evapotranspiration) PET peaks in July at 5.26 inches, coinciding with peak monsoon precipitation of 2.05 inches.

## 3.0 DESIGN CRITERIA

The design criteria for the expanded disposal cell are limited to the regulatory requirements, standards, and performance objectives that govern long-term containment of uranium mine-related waste materials. The criteria establish what the disposal cell must achieve and the technical requirements that must be satisfied; they do not describe the selected cover configuration or evaluate the adequacy of the design. The applicable objectives include protection of human health and the environment, long-term stabilization of waste materials, control of radiological and non-radiological releases, protection of groundwater and surface water, resistance to erosion and intrusion, and maintenance of physical stability throughout the required performance period.

The principal federal requirements are established by the Uranium Mill Tailings Radiation Control Act (UMTRCA), EPA standards in 40 CFR Part 192, and NRC requirements in 10 CFR Part 40, Appendix A. These regulations require disposal systems for uranium byproduct materials to provide effective stabilization and control for 1,000 years to the extent reasonably achievable, and in any case for at least 200 years. They also require reclamation plans to demonstrate compliance with applicable technical criteria for siting, decommissioning, reclamation, groundwater protection, radon control, long-term surveillance, and protection of public health, safety, and the environment.

Radiological performance criteria require control of residual radioactive materials and limitation of radon-222 emissions from the disposal cell surface. The applicable radon-222 flux performance objective is 20 $pCi/m^2/s$, consistent with the uranium mill tailings standards and NRC implementation requirements. The disposal cell must also prevent releases that would result in unacceptable radiation exposure to the public or workers and must support compliance with applicable radiation protection standards during closure, post-closure, and long-term surveillance.

Groundwater and surface-water performance criteria require the disposal cell to limit contaminant migration and avoid degradation of water resources beyond applicable regulatory standards. The criteria include minimizing net infiltration through the cover, preventing sustained ponding on the reclaimed surface, controlling contact between precipitation and waste materials, and managing runoff so that erosion, sediment transport, and contaminant release are limited. Applicable groundwater protection standards include the requirements of 40 CFR Part 192 and the groundwater-related criteria incorporated into 10 CFR Part 40, Appendix A.

Geotechnical and physical-stability criteria require the disposal cell to remain stable under static, seismic, settlement, and long-term degradation conditions. The relevant performance objectives include maintaining stable slopes, limiting differential settlement and cracking, avoiding conditions that could compromise containment, and accounting for site-specific geology, topography, hydrology, and meteorology. Stability evaluations must use appropriate design loads, material properties, and factors of safety consistent with applicable NRC guidance, accepted geotechnical practice, and site-specific hazard information.

Erosion-control, biointrusion, and cover-integrity criteria require the disposal cell to resist wind and water erosion, discourage plant-root and animal intrusion into containment layers, and maintain protective functions for the required performance period. Technical guidance for uranium tailings reclamation, including NRC standard review guidance and erosion-protection guidance, establishes expectations for long-term geomorphic stability, surface protection, drainage performance, material durability, and maintenance needs. Where rock armor is used for erosion protection, the rock layer thickness should be no less than the spherical diameter of the upper-limit $D_{100}$ rock or at least 1.5 times the diameter of the upper-limit $D_{50}$ rock, whichever is larger.

DOE (1988) expanded Sherard's criteria with these additions:

- Filter material should pass a 3-in. (76.2-mm) sieve to avoid particle segregation and bridging during installation; smaller maximum sizes may be used if needed. Filters should not have over 5% passing the No. 200 mesh sieve to prevent excess fine movement within the filter.
- Filter material needs to be well graded throughout.
- Filters for gap-graded bases may need finer grading than Sherard's basic criteria suggest.
- The minimum filter thickness should be 6 inches (152.4 mm) to aid placement.

Cover water-balance criteria should be evaluated against the overall performance objective of minimizing net percolation and protecting groundwater. For uranium-related disposal, the governing criteria remain the federal uranium tailings requirements and approved permit conditions. The New Mexico Copper Rule, 20.6.7.33 NMAC, is not directly applicable to a uranium mine disposal cell; however, it provides a relevant state benchmark for store-and-release cover performance at mine facilities with potential leachate generation. The rule requires, for covered copper mine units, an earthen store-and-release cover suitable for vegetation, erosion-resistant performance, and percolation control, generally including 36 inches of earthen material unless a reduced or alternative cover is justified.

The New Mexico Copper Rule (N.M. Code R. § 20.6.7.33) outlines specific cover thickness requirements for the closure of copper mine facilities, summarized as follows:

- Upon closure, waste rock piles, leach stockpiles, tailing impoundments, and other units with potential for leachate generation must be covered using a store-and-release earthen cover system.
- The required cover must consist of 36 inches (3 feet) of earthen material suitable for sustaining vegetation without ongoing supplementation and featuring erosion-resistant properties.
- The system should minimize net percolation by retaining at least 95% of long-term average winter precipitation or 35% of long-term average summer precipitation, whichever is higher.
- Erosion rates should be comparable to those found on stable slopes in the surrounding landscape.

Cover thickness may be reduced when placed over lined units, or if an alternative design offers equivalent or improved groundwater protection. Such alternatives necessitate a robust modeling study, an appropriate performance monitoring plan, and independent third-party review.

Proper compaction of waste and cover materials is necessary to avoid settlement and maintain structure. Quality control procedures (like moisture-density tests) are performed during construction. CQC and CQA plans will be submitted to NMED for approval a minimum of 30 days prior to beginning of construction of the clay liner. Within 60 days following completion of construction of the clay liner, a CQA report and as-built plans shall be submitted to NMED. Designs must allow for monitoring and addressing subsidence or deformation over time, and all elements should be chosen for long-term chemical and physical stability suitable for local conditions. Finally, the cell must remain accessible for periodic inspection, maintenance, and environmental monitoring.

# 4.0 EXPANDED DISPOSAL CELL DESIGN

## 4.1 General

Reclamation of the waste rock and associated cleanup material is organized into two distinct phases, each designed to promote structural stability, effective drainage, and long-term environmental protection.

This report presents an optimized cover system based on updated analyses completed in July 2026. The optimized cover system consists of a three-layer configuration totaling 52 inches: 12 inches of rock mulch, 28 inches of on-site soil cover, and a 12-inch compacted clay radon barrier. The revised design meets or exceeds applicable regulatory performance requirements, as demonstrated in Sections 4.3 through 4.9 and detailed in Appendices E through I.

The integrated disposal cell cover is engineered to address frost penetration, radon attenuation, biointrusion, infiltration, surface water control, slope stability, and erosion protection, as detailed in Sections 4.3 through 4.9. The revised three-layer system consists of: (1) a 12-inch rock mulch

layer for erosion control; (2) a 28-inch on-site soil cover layer for biointrusion protection, frost buffering, and store-and-release moisture storage; and (3) a 12-inch compacted clay radon barrier for radon attenuation and infiltration control. Cover performance has been validated against applicable regulatory and design criteria, including radon flux below the 20 pCi/m²/s limit, frost-depth protection of the clay barrier, design-basis percolation of 0.40 in/yr, and PMP-based erosion resistance for unsupported slope runs up to 250 feet.

The reclamation and cover system addresses the applicable federal uranium tailings performance requirements in 40 CFR Part 192 and 10 CFR Part 40, Appendix A, Criterion 6, and uses the New Mexico Copper Rule (20.6.7.33 NMAC) as a relevant state performance benchmark for store-and-release cover behavior.

## 4.2 Description of Cover

After filling and grading, the expanded disposal cell cover will be placed over the waste material. The final cover system will consist of the following layers, from top to bottom:

- 12 inches of rock mulch cover for erosion protection
- 28 inches of on-site soil cover for biointrusion and frost protection
- 12 inches of compacted clay to minimize infiltration and radon gas emanation

A schematic of the revised cover is illustrated in Figure 4-1.

## 4.3 Frost Penetration Analysis

EA evaluated frost penetration depth into the expanded disposal cell cover, as explained in Appendix D. Using a method developed by the U.S. Department of Energy (DOE, 1989) and endorsed by the Nuclear Regulatory Commission, the analysis considered local climate, soil type, and moisture levels over the lifetime of the cover. The approach, based on Berggren's work (1943), uses site-specific calculations to estimate frost depth. Smith and Rager (2002) advanced these ideas to determine the required thickness of protective soil above compacted layers to shield against frost. All derivations and thermal parameter values are provided in Appendix D.

The analysis used a 200-year recurrence interval Air Freezing Index (AFI) of 927.5°F·days, corresponding to the design-basis value at the 200-year return period. The statistical comparison of 2018–2025 site climate data presented in Appendix F confirms that the design-basis AFI exceeds the highest observed site AFI (524 degree-days in 2022) by a substantial margin, providing confidence that the design freeze event is appropriately conservative.

The optimized cover system provides 28 inches of on-site soil cover above the clay radon barrier, matching the design frost depth. The on-site soil cover layer serves as the primary thermal buffer, ensuring the clay radon barrier remains below the active frost zone under the design freeze event. The rock mulch surface layer provides additional thermal damping. Engineering implications are as follows: the clay radon barrier remains below the 28-inch frost depth and is protected from freeze-thaw cycling; the small μ value indicates frost penetration is relatively insensitive to

moderate variations in soil thermal properties; and the revised frost depth supports the reduced cover thickness without compromising radon attenuation or long-term barrier performance.

## 4.4 Radon Attenuation

### 4.4.1 *Regulatory Standard*

The engineered cover system over the expanded disposal cell is required to limit the surface flux of radon-222 to no more than 20 pCi/m²/s averaged over the disposal cell surface, as established under 40 CFR Part 192 and 10 CFR Part 40, Appendix A, Criterion 6. Radon attenuation modeling was performed to confirm that the proposed three-layer cover system satisfies this standard.

### 4.4.2 *Cover System Configuration*

The three-layer cover system evaluated in the radon attenuation analysis consists of the following layers, from top to bottom:

- 12 inches (30.5 cm) of rock mulch for erosion protection (uppermost layer)
- 28 inches (71.1 cm) of on-site soil for biointrusion and frost protection
- 12 inches (30.5 cm) of compacted clay as the primary radon barrier

The contaminated materials below the cover are assumed to be 5 meters (16.4 feet, or approximately 197 inches) thick for modeling purposes. The cover system configuration is shown in Figure E-1 (Appendix E).

### 4.4.3 *Model Description*

Radon emanation calculations were performed using the Wise Uranium Project Uranium Mill Tailings Cover Calculator, which implements the one-dimensional steady-state radon diffusion model described in NRC Regulatory Guide 3.64 (NRC, 1989). The model evaluates radon-222 diffusion from a radium-226 source through layered cover materials and computes the exit radon flux at the top of each layer. The calculator was executed in metric units with four model layers: contaminated materials, clay radon barrier, on-site soil, and rock mulch.

The key input parameters for the model are layer thickness, radium-226 activity concentration for the contaminated materials layer, radon emanation coefficient, porosity, long-term moisture content, and radon diffusion coefficient calculated by the model from material properties.

### 4.4.4 *Input Parameters*

#### 4.4.4.1 *Radium-226 Activity Concentration*

Radium-226 activity concentrations were derived from static gamma radiation surveys conducted by AVM Environmental Services, Inc. (AVM) across five distinct source area zones within the mine site. The representative mean activity values for each source area are summarized in Table 4-1.

**Table 4-1 Representative Ra-226 Activity Concentrations by Source Area**

| Source Area | Survey Date(s) | No. of Survey Locations | Mean Ra-226 Activity (pCi/g) | Reference |
|---|---|---|---|---|
| Windblown Area (WA) | May 17 and May 31, 2023 | 12 | 9.8 | AVM (2023) |
| Ore Pad Area (OPA) | May 31, 2023 | 5 | 431.6 | AVM (2023) |
| Mine Compound Area (MCA) | May 18–May 31, 2023 | 20 | 13.1 | AVM (2023) |
| Pond Area (PA) | October 18, 2023 | 40 | 4.8 | AVM (2024) |
| North Controlled Area (NCA) | September 19–December 12, 2024 | 47 | 47.1 | AVM (2025) |
| Arithmetic Mean (all areas) | — | 124 (total) | 101.3 | Calculated |

The arithmetic mean Ra-226 activity across all five source areas is approximately 101 pCi/g. For modeling purposes, a conservative design value of 115 pCi/g was used for the contaminated materials layer, which exceeds the five-area mean by 14 percent. This conservative assumption bounds the potential variability in source material composition across the disposal cell footprint. It is recommended that materials from the Ore Pad Area, which exhibit the highest mean Ra-226 activity (431.6 pCi/g), be placed at the base of the disposal cell during construction to minimize the thickness of high-activity materials near the cover interface.

#### 4.4.4.2 *Radon Emanation Coefficient*

A radon emanation coefficient of 0.35 was applied to all modeled layers, including the contaminated materials and cover materials. This is the conservative default value specified in the Uranium Mill Tailings Cover Calculator, consistent with NRC Regulatory Guide 3.64 (NRC, 1989).

#### 4.4.4.3 *Density and Porosity*

Material densities were assigned as follows: contaminated materials, 100 pcf (1.60 g/cm³), representative of a mixed sand, silt, and clay waste mass; clay radon barrier, 99 pcf (1.59 g/cm³), corresponding to 90 percent of the standard Proctor maximum dry density of sample EA-BSC09 (silty clay) collected from Borrow Area A-B in January 2025; on-site soil, 94 pcf (1.51 g/cm³), corresponding to 85 percent of the mean standard Proctor maximum dry density of samples EA-BSB04 (sand), EA-BSC12 (sandy clay), and EA-BSC09 (silty clay) from Borrow Area A-B; and rock mulch, 94 pcf (1.51 g/cm³), consistent with the on-site soil layer because the soil matrix of the rock mulch admixture is anticipated to be of similar composition.

Porosity values were assigned as follows: contaminated materials, 0.35, assumed for mixed sand, silt, and clay; clay radon barrier, 0.38, derived from the compaction test report for sample EA-BSC09 (void ratio = 0.62; porosity = e/(1+e) = 0.38); in-situ soil, 0.35, assumed for mixed sand, silt, and clay; and rock mulch, 0.35, consistent with the in-situ soil layer.

#### 4.4.4.4 *Long-Term Moisture Content*

Long-term moisture contents were assigned as follows: On -site soil and rock mulch, 6 percent, consistent with NRC guidance for long-term dry cover conditions (NRC, 1989). Clay radon barrier, 15.1 percent, determined from the soil water characteristic curve 15-bar permanent wilting point moisture content for sample EA-BSC09 (silty clay) remolded to 90 percent of standard Proctor density. Contaminated materials, 15.1 percent, equal to the clay barrier long-term moisture because the waste materials are below the depth of influence of surface evapotranspiration.

The long-term moisture content of the clay radon barrier is a sensitive model parameter. Use of the 15-bar SWCC moisture content is conservative and represents the equilibrium moisture condition under sustained drying; it produces a higher diffusion coefficient and therefore a higher, more conservative, radon flux estimate relative to higher moisture content assumptions.

#### 4.4.4.5 *Radon Diffusion Coefficient*

Radon diffusion coefficients for each layer were calculated internally by the Uranium Mill Tailings Cover Calculator based on the assigned porosity and long-term moisture content, consistent with the methodology of NRC Regulatory Guide 3.64 (NRC, 1989). The resulting diffusion coefficients are $1.69 \times 10^{-7}$ m²/s for contaminated materials, $4.62 \times 10^{-7}$ m²/s for the clay radon barrier, $2.01 \times 10^{-6}$ m²/s for the on-site soil layer, and $2.01 \times 10^{-6}$ m²/s for the rock mulch.

The clay radon barrier has a diffusion coefficient approximately 4.3 times lower than the on-site soil layer, reflecting the combined effect of higher density, higher moisture content, and finer texture. Lower diffusion coefficients correspond to lower radon transport rates through the layer.

### 4.4.5 *Model Results*

The input parameters and model results are summarized in Table 4-2. Full model output is provided in Appendix E. The radon attenuation model results indicate that the three-layer cover system reduces the radon-222 surface flux from a bare-source flux of 42.10 pCi/m²/s to a design surface flux of 13.99 pCi/m²/s at the top of the rock mulch layer. The total cover retention efficiency is 66.77 percent. The calculated surface flux of 13.99 pCi/m²/s is 30 percent below the NRC regulatory limit of 20 pCi/m²/s, confirming that the proposed cover system satisfies the radon attenuation performance standard.

The clay radon barrier provides the dominant attenuation effect, reducing flux from 31.17 pCi/m²/s at the top of the contaminated materials to 22.22 pCi/m²/s at the top of the clay layer. The on-site soil layer provides additional attenuation from 22.22 pCi/m²/s to 14.67 pCi/m²/s. The rock mulch layer provides the final attenuation step from 14.67 pCi/m²/s to 13.99 pCi/m²/s at the exposed surface. The progressive reduction in flux through each layer is consistent with the physics of one-dimensional steady-state diffusion and confirms the layered design is functioning as intended.

**Table 4-2 Radon Attenuation Model Input and Results**

| Layer No. | Layer Description | Thickness (in) | Porosity | Ra-226 Activity (pCi/g) | Emanation Coefficient | Diffusion Coeff. ($m^2/s$) | Exit Radon Flux ($pCi/m^2/s$) |
|---|---|---|---|---|---|---|---|
| 4 | Rock mulch | 12 | 0.35 | 0 | 0.35 | $2.01\times10^{-6}$ | 13.99 |
| 3 | On-site soil (frost protection and biointrusion) | 28 | 0.35 | 0 | 0.35 | $2.01\times10^{-6}$ | 14.67 |
| 2 | Clay layer (radon barrier) | 12 | 0.38 | 0 | 0.35 | $4.62\times10^{-7}$ | 22.22 |
| 1 | Contaminated materials | 197 | 0.35 | 115 | 0.35 | $1.69\times10^{-7}$ | 31.17 (bare source: 42.10) |

### 4.4.6 *Sensitivity Simulation*

Table 4-3 contains the results of the sensitivity analyses cases based on the Appendix E cover configuration and base radon flux of 13.99 $pCi/m^2/s$ for the 12-inch compacted clay barrier overlain by 28 inches of on-site soil cover. Consistent with the approach described in the Radon Attenuation Handbook for Uranium Mill Tailings Cover Design, the sensitivity cases evaluate how variations in on-site soil cover thickness, clay barrier thickness, and effective radon diffusion coefficients influence flux through the layered earthen cover system.

The revised sensitivity results summarized in Table 4-3 indicate that the base design flux of 13.99 $pCi/m^2/s$ provided in Appendix E remains below the 20 $pCi/m^2/s$ regulatory criterion. The on-site soil cover thickness cases show that reducing the overlying soil thickness increases calculated flux by shortening the diffusion path length, while increasing the thickness provides additional attenuation. The clay barrier thickness cases show that the compacted clay layer remains the controlling attenuation element because reduced clay thickness produces a larger loss of margin than a comparable change in the overlying on-site soil cover. The diffusion coefficient cases show that less favorable effective diffusion behavior increases calculated flux, while lower effective diffusion coefficients improve performance. All evaluated cases remain below the regulatory criterion, but the reduced clay and higher diffusion coefficient cases have the smallest margins and therefore define the most important construction quality control checks.

**Table 4-3 Results of Radon Sensitivity Analysis**

| Case | On-Site Soil Cover Thickness (in) | Clay Barrier Thickness (in) | Radon Diffusion Coefficient Assumption | Surface Flux (pCi/m²/s) |
|---|---|---|---|---|
| Appendix E base design | 28 | 12 | Appendix E design value | 13.99 |
| Reduced on-site soil cover | 20 | 12 | Appendix E design value | 16.21 |
| Increased on-site soil cover | 36 | 12 | Appendix E design value | 12.08 |
| Reduced clay barrier | 28 | 9 | Appendix E design value | 17.62 |
| Higher diffusion coefficient | 28 | 12 | 1.5 × Appendix E value | 18.74 |
| Lower diffusion coefficient | 28 | 12 | 0.75 × Appendix E value | 11.34 |

Model sensitivity testing indicates that radon flux is not strongly sensitive to the porosity of the waste materials, on-site soil, or rock mulch layers. However, the clay radon barrier porosity is a sensitive parameter: a 20 percent reduction in clay porosity reduces calculated flux to near zero, while a 20 percent increase can approximately double the calculated flux. The design clay porosity of 0.38 is based on laboratory data and is considered representative of the as-compacted condition.

## 4.5 Biointrusion

### 4.5.1 *Regulatory Framework*

The disposal cell cover system is designed to satisfy the biointrusion-relevant requirements of the U.S. Nuclear Regulatory Commission (NRC) under 10 CFR Part 40, Appendix A, Criterion 6, and the U.S. Environmental Protection Agency (EPA) under 40 CFR Part 192. Under Criterion 6 of 10 CFR Part 40, Appendix A, the cover system must provide reasonable assurance of control of radiological hazards for 1,000 years to an extent reasonably achievable, and in any case for at least 200 years. The New Mexico Environment Department (NMED) implementing regulations are consistent with these federal standards.

10 CFR Part 40, Appendix A, Criterion 6 further requires that either a full self-sustaining vegetative cover or rock cover be established to reduce wind and water erosion to negligible levels. In semi-arid and arid regions where a self-sustaining vegetative cover is not reliably achievable, rock cover must be employed on impoundment slopes. The Mt. Taylor disposal cell uses rock mulch on all exposed slopes consistent with this requirement, as described in Section 4.2.

### 4.5.2 *Role of Vegetation in Store-and-Release Cover Performance*

While not necessary, proposed, nor modeled in EA's infiltration analyses the current NRC and DOE guidance on evapotranspiration (ET) and store-and-release (SAR) cover systems recognizes that shallow-rooted native vegetation is a functionally integral component of cover performance. Native grasses and forbs with shallow root systems actively remove stored soil moisture through transpiration, thereby enhancing the cover's water-balance performance and reducing the fraction of precipitation available for deep percolation. This is consistent with the passive SAR design philosophy adopted for the Mt. Taylor disposal cell.

The primary biointrusion concern is the potential for deep-rooted woody plants, including shrubs and trees, and burrowing mammals to penetrate and compromise the clay radon barrier. The cover design addresses these threats through the physical deterrents described in Section 4.5.3, and the revegetation plan in Section 4.13 restricts planting to shallow-rooted native grass species consistent with the semi-arid climate.

### 4.5.3 *Cover System Design Measures Against Biointrusion*

The three-layer, 52-inch cover system provides redundant physical deterrents against biointrusion while maintaining the erosion-control, water-balance, and radon-attenuation functions of the final cover. Biointrusion protection is achieved through a combination of a coarse rock mulch surface that discourages animal burrowing, a compacted on-site soil cover layer that separates routine biological activity from the radon barrier, and a compacted clay layer that provides the low-permeability and low-diffusivity containment function at the base of the cover.

**Rock Mulch Layer (12 inches, uppermost).** The rock mulch layer is the first line of defense against biological disturbance. In addition to resisting wind and water erosion, the coarse, discontinuous surface reduces the suitability of the cover as burrowing habitat and makes excavation by small to medium burrowing animals more difficult. The rock mulch admixture consists of 30 percent AASHTO No. 1 gravel and 70 percent on-site soil, provides a durable surface layer while retaining sufficient fines to support the intended revegetation strategy.

**On-Site Soil Cover Layer (28 inches).** The compacted on-site soil cover layer provides the primary separation distance between surface biological activity and the compacted clay radon barrier. This layer can support shallow-rooted native grass community, provides frost buffering above the clay layer, and limits the likelihood that routine root growth, insect activity, or shallow animal disturbance will reach the radon barrier. The 28-inch thickness is therefore a key design feature because it maintains physical separation while preserving the store-and-release function of the cover.

**Compacted Clay Radon Barrier (12 inches).** The compacted clay layer is the principal radon-attenuation and infiltration-control layer and is protected from direct biological contact by the overlying 40 inches of rock mulch and on-site soil cover. Its cohesive texture, compacted condition, and low saturated hydraulic conductivity of $7.6\times10^{-6}$ cm/s reduce the likelihood of root penetration, insect excavation, and preferential pathway formation. Maintaining the continuity,

thickness, moisture condition, and compaction of this layer during construction is essential to preserving the biointrusion, radon-control, and infiltration-control functions of the cover system.

### 4.5.4 *Post-Closure Monitoring and Adaptive Management*

Post-closure stewardship will include periodic inspection of the cover surface for evidence of biointrusion, including the establishment of deep-rooted woody vegetation, active burrowing activity, and visible cracking or surface disturbance. Inspection frequency and corrective action thresholds will be established in the Post-Closure Stewardship Plan consistent with NRC and NMED requirements. Corrective actions may include manual removal of encroaching woody vegetation, backfilling of burrow openings, and localized cover repair as needed to maintain the integrity of the radon barrier and overall cover system.

The adaptive management framework is designed to detect and address biointrusion before cumulative damage to the cover system can occur, consistent with the long-term performance objectives of 10 CFR Part 40, Appendix A, Criterion 6.

## 4.6 Infiltration Analysis

### 4.6.1 *General*

The infiltration analysis evaluates long-term percolation through the engineered cover system and compliance with the New Mexico Copper Rule (20.6.7.33 NMAC) store-and-release performance standard. The cover system is designed as a passive store-and-release (SAR) barrier that relies on the soil moisture storage capacity of the on-site soil cover layer and the prevailing semi-arid climate to limit deep percolation into the underlying waste. The analysis integrates site-specific climate data, analytical water balance methods, and numerical seepage modeling.

### 4.6.2 *Method of Analysis*

The infiltration assessment employs a two-tiered approach:

1. Analytical Water Balance — The Budyko (1948) exponential equation is applied to estimate annual actual evapotranspiration (AET). Surface runoff is estimated using the Soil Conservation Service (SCS) Curve Number method applied on a monthly time step. Annual percolation is derived as the residual of precipitation minus AET and surface runoff.
2. Numerical Seepage Model (SEEP/W) — A two-dimensional transient finite-element model was developed using GeoStudio SEEP/W to simulate unsaturated and saturated flow through the proposed cover profile. Model results provide the adopted design-basis percolation rate. Model inputs, boundary conditions, and results are summarized in Appendix G.

The analytical water balance provides an independent upper-bound estimate of percolation to bracket SEEP/W results and confirm that the numerical model is reasonable.

### 4.6.3 *Parameters Used for Analysis*

Table 4-4 contains a summary of the monthly distribution of precipitation and PET for the 2018–2025 San Mateo station record. The data show a strong seasonal water-balance pattern: precipitation is greatest during the summer monsoon period, particularly July through September, but PET also reaches its maximum during the same interval. As a result, every month from March through October exhibits a moisture deficit, with the largest monthly deficits occurring in June, July, and August. Positive monthly balances occur only during the low-PET winter months and are small in magnitude. On an annual basis, precipitation totals 10.01 inches compared with 26.45 inches of PET, producing a net annual moisture deficit of 16.44 inches. This monthly pattern indicates that stored soil water is expected to be depleted during the growing season, limiting the amount of water available for sustained downward percolation through the cover profile.

Soil hydraulic parameters, climate inputs, and SCS runoff parameters used in the analytical water balance and numerical seepage model are summarized in Table 4-5. Laboratory test methods and data reduction procedures are documented in Appendix B; climate data derivation is documented in Appendix F.

**Table 4-4 Monthly Climate Water Balance**

| Month | Precipitation, P (in) | PET (in) | Surplus / Deficit (in) |
|---|---|---|---|
| January | 0.38 | 0.00 | +0.38 |
| February | 0.26 | 0.16 | +0.10 |
| March | 0.48 | 0.69 | −0.21 |
| April | 0.28 | 1.76 | −1.48 |
| May | 0.71 | 3.15 | −2.44 |
| June | 0.94 | 4.74 | −3.80 |
| July | 2.05 | 5.26 | −3.21 |
| August | 1.71 | 4.70 | −2.99 |
| September | 1.45 | 3.46 | −2.01 |
| October | 0.86 | 1.83 | −0.97 |
| November | 0.59 | 0.57 | +0.02 |
| December | 0.30 | 0.13 | +0.17 |
| **Annual Total** | **10.01** | **26.45** | **−16.44** |

**Table 4-5 Soil and Climate Parameters Used for the Infiltration Analysis**

| Parameter | Layer / Station | Value | Source |
|---|---|---|---|
| Saturated hydraulic conductivity, ksat | On-site soil cover | 1.2×10−4 cm/s | Lab testing, Appendix B |
| Saturated hydraulic conductivity, ksat | Compacted clay barrier | 7.6×10−6 cm/s | Design specification |
| Volumetric water content at field capacity, θfc | On-site soil cover (CL-ML) | 0.20 | SWCC, Appendix B |
| Volumetric water content at wilting point, θwp | On-site soil cover (CL-ML) | 0.10 | SWCC, Appendix B |
| Available water holding capacity, AWHC | On-site soil cover | 0.10 in/in | θfc − θwp |
| SCS Curve Number, CN | Cover surface (rock mulch, rangeland HSG B) | 55 | TR-55 (USDA, 1986) |
| Mean annual precipitation, P | San Mateo on-site station | 10.01 in/yr | Appendix F (2018–2025) |
| Potential evapotranspiration, PET | Thornthwaite (1948) | 26.45 in/yr | Appendix F |

### 4.6.4 *Water Balance Components and Percolation Estimation*

#### 4.6.4.1 *Aridity Index*

The ratio of potential evapotranspiration to mean annual precipitation characterizes the degree of water limitation at the site. The dimensionless aridity index φ is defined as:

$$\varphi = \text{PET} / P = 26.45 / 10.01 = 2.64$$

An aridity index greater than 2.0 indicates a strongly water-limited environment. Under these conditions, the dominant fate of infiltrated precipitation is evapotranspiration rather than deep percolation or runoff. The site value of 2.64 is consistent with the semi-arid character of the San Mateo area in northwestern New Mexico.

#### 4.6.4.2 *Actual Evapotranspiration*

Actual evapotranspiration (AET) was estimated using the Budyko (1948) exponential equation, which captures the long-term partitioning of precipitation between evapotranspiration and drainage under water-limited conditions:

$$\text{AET} = P(1 - e^{-\text{PET}/P})$$

Substituting the site-specific annual precipitation and PET values from Table 4-4:

$$\text{AET} = 10.01(1 - e^{-2.64}) = 10.01(1 - 0.071) = 10.01 \times 0.929 = 9.30 \text{ in/yr}$$

This result is consistent with the expectation that AET approaches MAP in a strongly arid climate, as the available soil water is nearly completely depleted through evapotranspiration before deep

drainage can occur. The fraction of precipitation lost to AET is 92.9 percent, leaving a limited residual available for surface runoff or percolation.

#### 4.6.4.3 *Surface Runoff*

Surface runoff was estimated using the SCS Curve Number method (USDA TR-55, 1986) applied on a monthly time step. A Curve Number of 55 was selected for rangeland conditions with rock mulch cover and Hydrologic Soil Group B soils, consistent with the cover surface description in Section 4.2. The maximum potential retention S and initial abstraction Ia are defined as:

$$S = 1000 / \mathrm{CN} - 10 = 1000 / 55 - 10 = 8.18 \text{ in}$$

$$I_a = 0.2S = 0.2 \times 8.18 = 1.64 \text{ in}$$

Runoff Q for any month with precipitation (Pm) greater than the initial abstraction threshold (Ia) is calculated as:

$$Q = (P_m - I_a)^2 / (P_m + 0.8S)$$

Applying the SCS Curve Number runoff equation to each month of the 2018–2025 mean monthly precipitation record shown in Table 4-4, only July (P = 2.05 in) and August (P = 1.71 in) exceed the threshold of 1.64 in. Monthly runoff calculations for the two generating months are as follows:

$$\text{July: } Q = (2.05 - 1.64)^2 / (2.05 + 0.8 \times 8.18) = 0.1681 / 8.594 = 0.0196 \text{ in} \approx 0.020 \text{ in}$$

$$\text{August: } Q = (1.71 - 1.64)^2 / (1.71 + 0.8 \times 8.18) = 0.0049 / 8.254 = 0.0006 \text{ in} \approx 0.001 \text{ in}$$

All remaining months produce no runoff because mean monthly precipitation does not exceed the initial abstraction threshold of 1.64 in. Annual surface runoff is the sum of monthly values:

$$R = \sum_{m=1}^{12} Q_m = 0.020 + 0.001 = 0.021 \text{ in/yr}$$

This low runoff magnitude is physically consistent with the rock mulch surface layer and semi-arid climate; the majority of precipitation events are low-intensity, sub-threshold occurrences that are fully retained within surface storage and subsequently lost to evapotranspiration.

#### 4.6.4.4 *Annual Percolation — Analytical Upper Bound*

Under steady-state annual conditions (ΔS = 0), the water balance residual provides an upper-bound estimate of potential deep percolation:

$$\text{Percolation} = P - \mathrm{AET} - R$$

$$\text{Percolation} = 10.01 - 9.30 - 0.021 = 0.689 \text{ in/yr} \approx 0.69 \text{ in/yr}$$

This result represents approximately 6.9 percent of mean annual precipitation and constitutes an analytical upper bound. The SEEP/W transient model accounts for unsaturated storage dynamics and produces a lower design-basis percolation value, as discussed in Section 4.6.6.

**Table 4-6 Annual Water Balance Summary**

| Component | Value (in/yr) | Percentage of MAP |
|---|---|---|
| Mean annual precipitation (P) | 10.01 | 100.0% |
| Actual evapotranspiration (AET) | 9.30 | 92.9% |
| Surface runoff (R) | 0.02 | 0.2% |
| Percolation — analytical upper bound (Eq. 4-8) | 0.69 | 6.9% |

Note: MAP = mean annual precipitation based on the 2018–2025 San Mateo on-site climate record summarized in Table 4-4 and Appendix D. Components may not sum exactly to 100% due to rounding.

### 4.6.5 *Copper Rule Store-and-Release Compliance*

Under the New Mexico Copper Rule (20.6.7.33 NMAC), a passive store-and-release cover system must demonstrate that the available water storage capacity of the soil layer equals or exceeds 95 percent of the mean winter precipitation or 35 percent of the mean summer precipitation, whichever is greater. This standard ensures that the cover can buffer episodic precipitation events without allowing percolation into the underlying waste mass.

#### 4.6.5.1 *Seasonal Precipitation from Site Climate Record*

Seasonal precipitation totals were derived from the 2018–2025 San Mateo on-site climate record summarized in Table 4-4 and compiled in Appendix D. Seasonal periods follow the Copper Rule convention: winter season spans October through March; summer season spans April through September. Mean monthly precipitation values from the site record are applied to each seasonal summation.

Winter precipitation, $P_w$:

$$P_w = P_{Oct} + P_{Nov} + P_{Dec} + P_{Jan} + P_{Feb} + P_{Mar}$$

$$P_w = 0.86 + 0.59 + 0.30 + 0.38 + 0.26 + 0.48 = 2.87 \text{ in}$$

Summer precipitation, $P_s$:

$$P_s = P_{Apr} + P_{May} + P_{Jun} + P_{Jul} + P_{Aug} + P_{Sep}$$

$$P_s = 0.28 + 0.71 + 0.94 + 2.05 + 1.71 + 1.45 = 7.14 \text{ in}$$

#### 4.6.5.2 *Required Storage*

The Copper Rule storage requirement is the greater of the two seasonal threshold values:

$$S_{req} = \max(0.95P_w, 0.35P_s)$$

$$0.95P_w = 0.95 \times 2.87 = 2.73 \text{ in} \quad \text{(winter threshold)}$$

$$0.35P_s = 0.35 \times 7.14 = 2.50 \text{ in} \quad \text{(summer threshold)}$$

The winter threshold governs. The Copper Rule required storage is:

$$S_{req} = 2.73 \text{ in}$$

#### 4.6.5.3 *Storage Provided*

The 28-inch on-site soil cover layer provides water storage capacity determined by the available water holding capacity (AWHC) of the soil profile:

$$S_{cap} = \text{AWHC} \times d = 0.10 \text{ in/in} \times 28 \text{ in} = 2.80 \text{ in}$$

The provided storage of 2.80 in exceeds the required storage of 2.73 in by 0.07 in, confirming compliance with the New Mexico Copper Rule (20.6.7.33 NMAC) store and release performance standard under nominal design conditions.

#### 4.6.5.4 *Results of Infiltration Analysis*

The SEEP/W transient numerical model was developed using the cover profile described in Section 4.2. The model layout is shown on Figure 4-2. The model was applied using the daily precipitation records from the Gallup, NM weather station as the upper boundary condition, with atmospheric evapotranspiration prescribed using the Thornthwaite (1948) PET estimates summarized in Table 4-4. Material hydraulic properties are defined by the laboratory-derived soil-water characteristic curves (Appendix B) and the saturated hydraulic conductivity values in Table 4-5. Model inputs, boundary conditions, calibration, and output time series are documented in Appendix G.

Under the design precipitation record, the transient numerical model produces a long-term mean annual percolation rate of 0.40 in/yr at the base of the cover system, as documented in Appendix G. This design-basis rate is approximately 4.0 percent of mean annual precipitation and is below the analytical upper bound of 0.69 in/yr, or 6.9 percent of mean annual precipitation, computed using the Budyko and SCS water balance in Section 4.6.4. The lower numerical result is physically consistent because the transient model captures unsaturated soil moisture storage during low-intensity precipitation intervals, thereby reducing the fraction of precipitation that reaches the compacted clay radon barrier. Together, the numerical design basis and analytical upper bound confirm that the cover system limits deep percolation to a small fraction of mean annual precipitation under site design conditions.

The analytical and numerical results together confirm that the proposed 52-inch three-layer cover system, comprising a 12-inch rock mulch surface layer, a 28-inch on-site soil cover storage layer, and a 12-inch compacted clay radon barrier, provides the hydrologic performance required under the design climate. Percolation through the cover is effectively controlled by the combined effects of high evapotranspirative demand, negligible surface runoff generation, and the moisture storage capacity of the on-site soil cover layer.

## 4.7 Settlement Analysis

Settlement of the compacted disposal cell will be evaluated during material placement. Before construction, representative waste samples will be collected, remolded to 95 percent of the standard Proctor maximum dry density, and tested for consolidation and swell under wetting conditions. These data will be used to confirm that sufficient camber has been incorporated into the final grading surface to maintain positive surface drainage. Tanks or other vessels that could collapse over time will be flow-filled or otherwise stabilized to limit potential future settlement.

## 4.8 Slope Stability Analysis

### 4.8.1 *General*

The slope stability assessment evaluates the global stability of the expanded disposal cell after placement of the final cover system. Detailed slope stability calculations, model output, and supporting figures are provided in Appendix H. The cover system is designed with exterior slopes of 5H:1V, equivalent to a 20 percent grade. Stability sections were developed to represent the combined new disposal cell configuration tied into the steepest section of the existing cell without terraces. This configuration provides a conservative assessment section for evaluating potential deep-seated and shallow translational failure mechanisms through the cover, waste, and foundation materials.

### 4.8.2 *Method of Analysis*

EA evaluated global stability using the Morgenstern-Price limit equilibrium method (Morgenstern and Price, 1965) in SLOPE/W (GeoStudio, 2021). The Figure 4-3 section represents the combined new disposal cell and steepest existing-cell section without terraces. Static and pseudo-static seismic cases were evaluated for circular and non-circular failure surfaces using target FOS values of 1.5 and 1.1, respectively. Model setup, search criteria, geometry, and supporting output are documented in Appendix H; results are shown in Figures 4-4 and 4-5.

Section 2.5 describes the probabilistic seismic hazard analysis for the facility, which indicates a peak horizontal ground acceleration (PGA) of 0.21g for a 10,000-year return period. For the pseudo-static analyses, a horizontal seismic coefficient of 0.14 was applied, corresponding to two-thirds of the 10,000-year PGA. This coefficient was applied as a horizontal inertial load in the seismic stability cases.

### 4.8.3 *Material Properties*

Material properties used in the stability analyses were selected from the lower band of available laboratory test results, design specifications, and conservative engineering judgment for materials in the analyzed section. This approach is consistent with the SLOPE/W assessment presented in Appendix H and avoids using average laboratory strength values where lower band values govern design. The material set represents the final cover system, compacted disposal cell fill and waste, and foundation soil or overburden. Bedrock is not included in the analyzed section and is therefore not represented as a separate model material. The adopted parameters are summarized in Table 4-7.

**Table 4-7 Material Properties Used for Stability Assessment**

| Material / Zone | Unit Weight, γ (pcf) | Cohesion, c′ (psf) | Friction Angle, φ′ (degrees) |
|---|---|---|---|
| Rock mulch cover | 115 | 0 | 35 |
| On-site soil cover | 110 | 0 | 25 |
| Compacted clay radon barrier | 120 | 0 | 24 |
| Compacted disposal-cell fill / waste | 102 | 0 | 25 |
| Foundation soil / overburden | 122 | 0 | 25 |

### 4.8.4 *Results of Analysis*

The stability results indicate that the combined disposal cell configuration with 5H:1V final cover slopes satisfy the applicable static and pseudo-static stability criteria for the analyzed section. The static analysis produced a factor of safety greater than the NRC target value of 1.5, and the pseudo-static seismic analysis using a horizontal coefficient of 0.14 produced a factor of safety greater than the target value of 1.1. These results indicate adequate global stability for the analyzed section, including the steepest existing-cell segment without terraces, using the material zones and lower band strength parameters summarized in Table 4-7. Detailed SLOPE/W output and supporting stability figures are provided in Appendix H; the summary results are presented in Figures 4-4 and 4-5.

## 4.9 Surface Water Hydrology and Erosion Protection

The reclaimed disposal cell surface is protected from water and wind erosion through a combination of offsite runoff diversion and rock mulch admixture surface facing. These two elements are designed independently and are discussed in separate subsections below. Erosion protection design follows the procedures specified in NUREG-1623 (NRC, 2002) and NUREG/CR-4620 (Nelson et al., 1986), which are the NRC-recommended standards for long-term stabilization of uranium mill tailings impoundments. The design life for the erosion protection system is 1,000 years, consistent with 40 CFR 192 and 10 CFR Part 40, Appendix A, Criterion 6. Supporting hydrology, hydraulic, rock mulch sizing, gully formation, stable-slope, riprap, filter-bedding, and wind-erosion calculations are provided in Appendix I.

### 4.9.1 *General*

The expanded disposal cell cover will be graded at a 20 percent slope, equivalent to 5H:1V, and will include a 12-inch-thick rock mulch surface layer composed of a rock-soil admixture. The admixture will consist of 30 percent AASHTO No. 1 gravel and 70 percent onsite on-site soil material by volume. This configuration provides durable erosion resistance under the site's semi-arid climate and high-intensity precipitation regime while supporting vegetation establishment through a soil matrix suitable for root development. Gravel-soil admixture covers used in analogous uranium mill tailings closures in the Grants Mineral Belt have effectively controlled water and wind erosion while allowing native vegetation to establish without materially reducing evapotranspiration. Erosion and water-balance studies support moderate gravel fractions,

generally 25 to 35 percent by volume, to meet the dual objectives of erosion control and evapotranspiration performance. As wind and water act on the admixture surface, fines are winnowed away, forming a vegetated desert pavement that provides long-term, self-reinforcing erosion resistance.

### 4.9.2 *Design Storm*

The design storm for long-term erosion stability is the Probable Maximum Precipitation (PMP), consistent with NUREG-1623 and NUREG/CR-4620. The PMP produces the Probable Maximum Flood (PMF), which governs rock mulch and riprap sizing for the 1,000-year erosion-protection design life. Appendix I provides design-storm selection, rainfall-depth development, and hydrologic calculations used for the cover and diversion channel evaluations.

The Mt. Taylor Mine site is located approximately 7,400 feet above mean sea level and west of the 103rd meridian. Therefore, the Appendix I calculation applies the NUREG/CR-4620 procedures for the generalized 6-hour storm and the local 1-hour, 1-square-mile storm. PMP rainfall depths were obtained from HMR-49 (NOAA, 1984), with elevation adjustments applied for site conditions and no drainage-area scale reduction for areas less than one square mile.

For cover design, the short-duration PMP governs the rock mulch erosion checks because the cover has short times of concentration. For the diversion channel, the PMP-derived PMF governs the longer-duration watershed response and channel lining design. The 100-year, 24-hour precipitation depth of 2.56 inches is documented in Appendix F, but Appendix I confirms that the PMP condition is substantially more severe and therefore governs erosion-protection design.

### 4.9.3 *Rock Mulch Cover Design*

#### 4.9.3.1 *Contributing Area and Time of Concentration*

Design flows for rock mulch sizing were computed using the Rational Method with contributing areas defined on a unit width basis to simulate sheet flow across the cover surface, consistent with NUREG-1623. The contributing area for each slope segment is therefore defined as 1 foot multiplied by the cumulative slope length from the ridgeline.

$$A = 1 \text{ ft} \times L$$

where $L$ is the cumulative slope length from the ridgeline. Time of concentration was calculated using the Kirpich (1940) formula as recommended in NUREG/CR-4620:

$$t_c = 0.0078 \times L^{0.770} \times S^{-0.385}$$

where $t_c$ is time of concentration in minutes, $L$ is slope length in feet, and $S$ is ground slope in feet per foot. At the design cover slope of 20 percent ($S$ = 0.20 ft/ft), the Kirpich formula yields short times of concentration for disposal cell cover slope segments. Where computed values fall below the minimum PMP duration increment used in NUREG/CR-4620, the minimum duration governs the applied rainfall intensity. The detailed slope-length increments, contributing areas, times of concentration, and governing rainfall intensities are provided in Appendix I.

#### 4.9.3.2 *Peak Discharge, Rational Method*

Peak runoff rates were computed using the Rational Method as recommended in NUREG-1623:

$$Q = C \times I \times A$$

where $Q$ is peak discharge in cfs per foot of unit width, $C$ is the runoff coefficient, $I$ is rainfall intensity in inches per hour, and $A$ is contributing area in acres per foot of width. A runoff coefficient of 0.80 was assigned to the rock mulch admixture cover surface, consistent with precedent for rock mulch cover surfaces. Appendix I provides the Rational Method worksheets used to calculate design discharges for the cover-slope erosion protection evaluation.

Velocity and flow depth on the cover surface were computed using Manning's equation for a wide rectangular flow section. A Manning's roughness coefficient of $n = 0.035$ was assigned to the rock mulch admixture cover, consistent with rocky soil cover surface guidance in NUREG/CR-4620.

#### 4.9.3.3 *Rock Mulch Sizing, Abt Johnson Method*

The median stone diameter of the rock mulch was sized using the Abt Johnson method, as recommended in NUREG-1623 and NUREG/CR-4620:

$$D_{50} = 5.23 \times q^{0.56} \times S^{0.43}$$

where $D_{50}$ is median rock size in inches, $q$ is unit discharge in cfs per foot, and $S$ is cover slope in feet per foot. A flow concentration factor of 3 is applied to the unit discharge to provide an appropriate degree of conservatism, consistent with NUREG-1623 guidance and comparable rock-mulch cover design practice. Appendix I documents the design discharges, flow depths, velocities, and computed $D_{50}$ values at representative slope-length increments. The results indicate that the AASHTO No. 1 gravel component, with a nominal $D_{50}$ of approximately 2.2 inches, provides adequate erosion resistance where unsupported slope runs are limited by interceptor berms or grade breaks. The adopted design standard limits maximum unsupported slope runs to 250 feet, providing a nominal factor of safety of at least approximately 1.08 for the provided gravel size based on the Appendix I Abt-Johnson calculations.

**Table 4-8 Rock Mulch Sizing Results**

| Slope Length L (ft) | Required D50 (in) | Provided D50 (in) | Factor of Safety |
|---|---|---|---|
| 50 | 0.83 | 2.20 | 2.65 |
| 100 | 1.22 | 2.20 | 1.80 |
| 150 | 1.54 | 2.20 | 1.43 |
| 200 | 1.80 | 2.20 | 1.22 |
| 250 | 2.04 | 2.20 | 1.08 |
| 300 | 2.26 | 2.20 | 0.97 |

As summarized in Table 4-8, the provided AASHTO No. 1 gravel $D_{50}$ of 2.20 inches exceeds the required $D_{50}$ for slope lengths up to 250 feet, but the factor of safety drops below unity at 300 feet. The rock mulch layer thickness is specified at 12 inches. Per NUREG-1623 guidance, the layer thickness must equal or exceed 1.5 times the $D_{50}$ diameter to prevent layer penetration under design

flow conditions. The 12-inch layer thickness exceeds 1.5 × 2.20 = 3.3 inches, satisfying this criterion by a wide margin.

#### 4.9.3.4 *Filter Requirement — Leps (1973)*

The need for a separate filter layer beneath the rock mulch admixture was evaluated in accordance with NUREG-1623 and NUREG/CR-4620 using the Leps (1973) relationship for interstitial flow through rockfill. The evaluation was completed to determine whether flow through the voids of the rock mulch could exceed filter-design thresholds and potentially require an additional transition layer between the rock mulch and the underlying on-site soil cover.

$$V_v = W_m^{0.5} \times i^{0.54}$$

In the Leps relationship, $V_v$ is the average interstitial velocity in the voids of rockfill, $W_m^{0.5}$ is an empirical coefficient dependent on rock size from the NUREG/CR-4620 tabulated values, and $i$ is the hydraulic gradient. For this evaluation, the hydraulic gradient was taken as the cover slope, $S$ = 0.20 ft/ft. Because the cover surface is a gravel-soil admixture rather than clean rockfill, the analysis was completed in two steps, as documented in Appendix I, Section I-3.

The first step provides a conservative screening calculation using only the AASHTO No. 1 gravel component. For the gravel fraction, $D_{50}$ = 2.20 inches and $W_m^{0.5}$ = 4.75 $in^{0.5}/s$. Substitution into the Leps equation at the design hydraulic gradient gives:

$$V_v = 4.75 \times (0.20)^{0.54} = 1.99 \text{ ft/s}$$

This screening value exceeds the NUREG-1623 threshold of 1.0 ft/s; however, it represents clean gravel behavior and is not the governing condition for the proposed cover. The constructed surface will be a blended admixture consisting of 30 percent AASHTO No. 1 gravel and 70 percent on-site soil cover material by volume. The fine-grained soil fraction fills the voids between gravel particles and controls the effective pore-throat dimension, so applying the gravel-only result directly would overstate the interstitial velocity through the constructed layer.

The second step therefore evaluates the blended admixture. On a simple volume-weighted basis, the blend of 30 percent gravel ($D_{50}$ = 2.20 inches) and 70 percent on-site soil cover material ($D_{50}$ = 0.0106 inches) gives:

$$D_{50,blend} = 0.30 \times 2.20 + 0.70 \times 0.0106 = 0.667 \text{ in}$$

As described in Appendix I, Section I-3.2.1, the effective blended $D_{50}$ for interstitial-flow behavior is governed by the finer on-site soil cover fraction rather than by the volume-weighted arithmetic value. On a mass-weighted and pore-control basis, the finer fraction fills the gravel voids and determines the effective pore size; therefore, the governing blended value is $D_{50,blend}$ = 0.0106 inches. Using this governing value, the corresponding Leps coefficient is:

$$W_m^{0.5} \ (D_{50} = 0.0106 \text{ in}) \approx 0.010 \ in^{0.5}/s$$

$$V_v = 0.010 \times (0.20)^{0.54} = 0.004 \text{ ft/s} << 1.0 \text{ ft/s}$$

The refined interstitial velocity of 0.004 ft/s is well below both the 1.0 ft/s screening threshold and the 0.5 ft/s no-filter threshold. This refined result is the governing Leps result for the constructed admixture because it reflects the effective pore structure created by the combined gravel and on-

site soil cover material. Accordingly, the blended admixture functions as its own filter at the interface with the underlying on-site soil cover, and a separate filter layer beneath the rock mulch cover is not required.

A Terzaghi (1943) filter-compatibility check was also completed to confirm that the admixture is compatible with the underlying on-site soil cover layer. The check was performed in accordance with Appendix I, Section I-3.2.3:

$$D_{15,\text{blend}} / D_{85,\text{subgrade}} = 0.045 \leq 5.0 \text{ [COMPATIBLE — criterion satisfied]}$$

The Terzaghi ratio is substantially below the criterion of 5.0, confirming compatibility between the blended admixture and the underlying on-site soil cover. The Leps and Terzaghi evaluations therefore support the same design conclusion: the rock mulch admixture provides adequate internal filtering and interface compatibility without a separate filter layer.

#### 4.9.3.5 *Gully Formation Analysis*

Gully formation within the rock mulch admixture cover was evaluated using NUREG-1623 and EPA (2012) guidance. Design flows for gully formation were computed using the Rational Method with a contributing area width equal to one quarter of the slope length, consistent with EPA (2012). Mean annual flow was estimated as 20 percent of the Probable Maximum Flood peak runoff:

$$Q_m = 0.20 \times Q_{PMF}$$

Gully channel geometry at the critical flow condition was estimated using EPA (2012) empirical equations relating mean annual flow, soil silt and clay content, and channel width-to-depth ratio. The percent silts and clays used in the calculation is the fraction passing the No. 200 sieve in the admixture gradation, approximately 17 percent for the 30 percent AASHTO No. 1 gravel and 70 percent on-site soil blend. Appendix I documents the gully-formation calculations, including mean annual flow, incipient particle size, armor-layer development, and calculated scour depth.

The incipient particle size was computed using Shield's equation:

$$D_c = \tau / [F_s \times (\gamma_s - \gamma)]$$

where $\tau$ is average bed shear stress, $F_s$ is Shield's dimensionless shear stress, $\gamma_s$ is specific weight of soil, and $\gamma$ is the unit weight of water. The depth of scour required to develop an armor layer was calculated using the Pemberton and Lara (1984) equation:

$$Y_s = Y_a \times [(1 / P_c) - 1]$$

where $Y_s$ is scour depth, $Y_a$ is armor-layer thickness, and $P_c$ is the decimal fraction of admixture material coarser than the incipient particle size. For the design slope length of 250 feet, the Appendix I Shield's incipient motion analysis yields a critical particle size of approximately 4.15 inches; gravel particles larger than that threshold resist movement and form the armor layer. The Pemberton-Lara equation yields a scour depth of approximately 10.3 inches, which is less than the 12-inch admixture layer thickness. Gully formation calculations therefore confirm that the armor layer develops within the depth of the rock mulch admixture before reaching the underlying on-site soil cover, protecting cover integrity under design flow conditions. This outcome also supports the adopted 250-foot maximum unsupported slope run because the calculated scour remains within

the sacrificial admixture layer before the design storm can expose the moisture-storage soil layer. Construction verification of gradation and thickness will be required to maintain this margin.

#### 4.9.3.6 *Stable Slope Analysis*

Long-term slope stability of the rock mulch admixture cover under PMP conditions was evaluated using two complementary approaches: the Abt-Johnson critical slope run length analysis, which governs the design, and the allowable shear stress method from Temple et al. (1987) and NUREG-1623, which provides a confirmatory check. The Abt-Johnson analysis establishes that the AASHTO No. 1 gravel component provides a factor of safety of approximately 1.08 at a slope length of 250 feet, declining below unity beyond approximately 286 feet. This establishes the governing design constraint that interceptor berms or grade breaks must be provided at a maximum spacing of 250 feet along the 20 percent cover slope.

$$\tau_a = 0.4 \times D_{75}$$

$$S_s^{7/6} = [65 \times \tau_a^{5/3}] / [I \times L \times F \times n]$$

where $S_s$ is maximum stable slope, $D_{75}$ is the 75th-percentile rock size in the admixture, $\tau_a$ is allowable shear stress, $I$ is PMP rainfall intensity, $L$ is slope length, $F$ is the flow concentration factor, and $n$ is Manning's roughness coefficient. For the AASHTO No. 1 gravel component, $D_{75}$ is approximately 3.5 inches, resulting in an allowable shear stress of approximately 1.40 psf. At the design cover slope and maximum berm spacing of 250 feet, computed bed shear stresses remain below the allowable shear stress, confirming the Abt-Johnson result. Stable-slope calculations are provided in Appendix I.

#### 4.9.3.7 *Rock Mulch Admixture Gradation*

The rock mulch admixture consists of 30 percent AASHTO No. 1 gravel and 70 percent on-site soil material by volume, consistent with EPA (2012) guidance for aggregate amended covers in arid and semi-arid environments. The 30 percent gravel fraction is specified to provide enhanced erosion resistance while maintaining sufficient finer soil matrix to support vegetation establishment. The gradations of the AASHTO No. 1 gravel, on-site soil material, and blended admixture are presented in Table 4-9.

**Table 4-9 Rock Mulch Admixture Gradation**

| Sieve Size | AASHTO No. 1 Gravel % Passing | On-Site Soil Material % Passing | Blended Admixture % Passing |
|---|---|---|---|
| 4 in (101.6 mm) | 100 | 100 | 100 |
| 3.5 in (88.9 mm) | 95 | 100 | 99 |
| 2.5 in (63.5 mm) | 50 | 100 | 85 |
| 1.5 in (38.1 mm) | 8 | 100 | 72 |
| 3/4 in (19.05 mm) | 3 | 100 | 71 |
| 3/8 in (9.525 mm) | 0 | 96 | 67 |
| No. 4 (4.76 mm) | 0 | 92 | 64 |
| No. 10 (2.00 mm) | 0 | 86 | 60 |
| No. 40 (0.420 mm) | 0 | 80 | 56 |
| No. 100 (0.149 mm) | 0 | 59 | 42 |
| No. 200 (0.074 mm) | 0 | 24 | 17 |

Note: Gradations are based on representative AASHTO No. 1 gravel and site on-site soil material used in the Appendix I erosion-protection calculations. Final admixture gradation shall be verified by blending trials before construction. The percent passing the No. 200 sieve in the blended admixture, approximately 17 percent, provides the silt and clay fraction input to the gully formation analysis in Section 4.9.3.5. The median size of the AASHTO No. 1 gravel component is nominally 2.2 inches, consistent with the specified gradation.

### 4.9.4 *Wind Erosion Analysis*

Wind erosion from the admixture cover surface was evaluated using the Wind Erosion Prediction System (WEPS), a USDA developed procedural simulation model that generates continuous weather simulations for site specific field conditions. WEPS produces an estimated annual soil loss in tons per acre per year. Site inputs for the WEPS analysis included site latitude, longitude, and elevation consistent with the site. A sandy loam soil with 30 percent rock fragment volume was used to represent the admixture surface. The 30 percent rock fragment input reflects the design gravel fraction and simulates the naturally developing armored surface expected on the cover over time.

EPA (1991) guidance for RCRA/CERCLA final covers identifies a soil loss target of less than 2 tons per acre per year as an acceptable benchmark for cover performance. The Mt. Taylor admixture design with 30 percent gravel will produce an annual erosion of 0.13 tons/acre/year. This is substantially below the 2-ton guidance threshold. Final site-specific WEPS results are provided in Appendix I.

### 4.9.5 *Summary*

The surface water hydrology and erosion protection design for the Mt. Taylor Mine expanded disposal cell integrates cover-slope armoring, gully-resistance checks, and wind-erosion protection. The design is based on the PMP/PMF framework and the procedures in NUREG-1623, NUREG/CR-4620, and 40 CFR Part 192, with supporting calculations provided in Appendix I. The resulting design limits erosion of the 20 percent cover slopes controls offsite inflow around the disposal cell and provides redundant protection at the diversion channel and embankment interface.

Table 4-10 summarizes the principal design elements and shows how each component contributes to the overall erosion-protection system. The design storm rows establish the hydrologic basis for the cover, using the local PMP storm for cover erosion. The time-of-concentration and peak-discharge rows identify the routing assumptions used to convert the design rainfall into cover-slope flow conditions, including the Kirpich equation, Rational Method, unit-width sheet-flow basis, and a runoff coefficient of 0.80 for the rock mulch admixture surface.

The table also documents the key erosion-resistance checks for the rock mulch cover. The Abt-Johnson rock-sizing method, with a flow concentration factor of 3, confirms that the AASHTO No. 1 gravel fraction provides adequate resistance for unsupported slope runs up to 250 feet. Manning's roughness value of 0.035 represents the rocky soil admixture surface used in the hydraulic calculations. The filter and gully-formation rows demonstrate that the blended rock-soil admixture functions as its own filter and that the calculated armor layer develops within the 12-inch rock mulch layer before scour reaches the underlying On-site soil cover.

**Table 4-100 Surface Water and Erosion Protection Design Summary**

| Design Element | Design Basis / Method | Key Parameter |
|---|---|---|
| Design storm for cover | PMP local storm from HMR-49 | West of 103rd meridian; site elevation approximately 7,400 ft |
| Time of concentration | Kirpich (1940), per NUREG/CR-4620 | Short cover times of concentration govern rainfall intensity |
| Peak discharge for cover | Rational Method with runoff coefficient $C = 0.80$ | Unit-width sheet-flow basis for cover slopes |
| Rock mulch size | Abt-Johnson method with flow concentration factor = 3 | $D_{50} = 5.23q^{0.56}S^{0.43}$; provided gravel $D_{50}$ approximately 2.2 in |
| Cover Manning's *n* | Rocky soil admixture surface | $n = 0.035$ |
| Cover filter requirement | Leps (1973) interstitial velocity and Terzaghi filter compatibility | Separate filter not required; admixture acts as filter |
| Gully formation | EPA (2012), Shields equation, and Pemberton and Lara (1984) | Armor layer develops within 12-inch rock mulch cover |
| Stable slope | Temple et al. (1987), NUREG-1623, and Abt-Johnson confirmation | Maximum unsupported slope run = 250 ft |
| Admixture design | 30 percent AASHTO No. 1 gravel and 70 percent on-site soil material | Nominal gravel $D_{50}$ approximately 2.2 in |
| Wind erosion | WEPS, USDA | Less than 2 tons/acre/year benchmark |

The rock mulch admixture protects the disposal cell surface from rainfall impact, sheet flow, gully formation, and wind erosion. These elements provide a technically consistent erosion-protection

design for the 1,000-year performance period, subject to construction verification of material gradations and layer thicknesses. This summary also provides a cross-check that the selected design assumptions are internally consistent across hydrology, hydraulics, gradation, filter compatibility, and long-term maintenance requirements, reducing the likelihood that any single component controls performance without supporting redundancy.

## 4.10 Borrow Source Location and Characterization

The disposal cell cover system will consist of (from bottom to top) clay radon barrier, on-site soil cover for biointrusion and frost protection, and a rock mulch layer for erosion protection. The proposed cover system is shown in Figure 4-1. This section discusses the location and characterization of the borrow source areas for the proposed cover materials.

### 4.10.1 *Borrow Source Locations*

The EA site investigation showed that the clay for the radon barrier and the on-site soil cover materials are procurable from the site. Figure 2-2 includes the locations of the potential borrow sources at the site.

### 4.10.2 *Borrow Source Characterization*

#### 4.10.2.1 *Clay Borrow Source*

The field investigation of the clay borrow source, conducted by EA, included excavation of 24 test pits as discussed in Section 2.3. The test pit locations are shown on Figure 2-3, and the test pit logs are included in Appendix A. EA encountered clay, silty clay, clayey silt, sandy clay, sand, and sandstone in the test pits.

#### 4.10.2.2 *On-Site Soil Cover Borrow Source*

A borrow source for the on-site soil cover exists at the Facility as shown on Figure 4-6. As discussed in Section 2.4.2, samples of the borrow source materials were collected for laboratory testing. The laboratory test results are included in Appendix B.

#### 4.10.2.3 *Rock Mulch Borrow Source*

The rock mulch cover layer will be locally sourced where suitable material is available. The material will comprise 30 percent AASHTO No. 1 gravel and 70 percent on-site soil cover material by volume. The source rock for the mixture may be imported if a suitable local source is not identified. NUREG-1623 provides specific criteria for the use of sandstone in reclamation applications, including fine-grained quartz cementation, low porosity, insignificant vertical and horizontal joints or fractures, and sourcing from massive bedding formations. Before final design, a borrow source for the rock will be identified and tested.

## 4.11 Borrow Source Quantities

The optimized 52-inch cover system requires three principal borrow material quantities: approximately 31,833 cubic yards of 12-inch rock cover, 70,620 cubic yards of 28-inch on-site soil cover, and 28,740 cubic yards of 12-inch compacted clay for the radon barrier. These quantities

are based on the revised cover configuration described in Section 4.2 and supersede the previous bulk borrow-source quantity estimate.

Borrow Source C has an approximate plan area of 522,920 square feet, or about 12.0 acres. Based on that area, each foot of recoverable material represents approximately 19,367 cubic yards of in-place soil before shrinkage, processing losses, oversize removal, or selective excavation. The required 28,740 cubic yards of compacted clay therefore corresponds to about 1.48 feet of average in-place clayey material across the Borrow Source C footprint before adjustment for construction yield. Allowing for approximately 15 percent loss or shrinkage, the required average recoverable thickness increases to about 1.70 feet.

The January 2025 test pit descriptions summarized in Section 2.3 indicate that sandy clay was encountered at most test pit locations and commonly occurs beneath the surficial sand at depths of approximately 3 to 4 feet, extending to the 6-foot exploration depth. Within Borrow Source C specifically, sandy clay was observed immediately below topsoil at C-2 and C-8, was present below sand at most other C-series test pits, and was absent at C-12 based on the limited excavation depth described in the logs. This distribution indicates that Borrow Source C contains a laterally extensive clayey soil interval, although the clayey material is not uniformly present from the ground surface and will require selective stripping of topsoil and overlying sand before excavation of the clayey borrow material.

For planning purposes, if the average recoverable clayey thickness within Borrow Source C is assumed to be 2.0 feet, the estimated available in-place clayey volume is approximately 38,735 cubic yards. If the average recoverable thickness is 2.5 feet, the estimated volume increases to approximately 48,419 cubic yards; at 3.0 feet, the estimated volume is approximately 58,102 cubic yards. These estimates indicate that Borrow Source C can reasonably supply the 28,740 cubic yards of compacted clay required for the 12-inch radon barrier if at least about 1.7 feet of suitable clayey material can be selectively recovered on average across the borrow area after allowances for shrinkage and unsuitable material.

The on-site soil cover requirement of 70,620 cubic yards is greater than the clay radon barrier requirement but may be satisfied using the overlying sand, sandy clay, and other suitable onsite on-site soil materials from Borrow Source C and other onsite borrow areas, subject to gradation, organic-content, oversize, moisture-density, and hydraulic suitability requirements. The 31,833 cubic yards of rock cover will be supplied from the approved rock mulch source or imported aggregate source and blended as specified in Section 4.9.

The borrow quantity estimate should be treated as preliminary because the uploaded test pit log file could not be read directly in this editing session. The estimate is therefore based on the test pit descriptions already summarized in Section 2.3 of this report. Before construction, Borrow Source C should be confirmed by field staking, additional shallow test pits or dozer cuts, laboratory classification and compaction testing, and construction quality assurance documentation to verify that the clayey material meets the compacted clay barrier specifications and that sufficient suitable volume remains after stripping and processing.

## 4.12 Revegetation of Disturbed Areas

Revegetation of the borrow areas will follow the Closeout/Closure Plan (EA, 2025) and use native, drought-adapted species suited to the Mt. Taylor Mine setting in the western plateau and high-valley region of northwestern New Mexico. The region receives approximately 10 to 14 inches of annual precipitation and supports native grassland and shrubland communities that include grama grasses, Indian ricegrass, galleta, and fourwing saltbush. The seed mix in Table 4-11 is appropriate for the Mt. Taylor Mine because it emphasizes shallow- to moderately rooted native grasses, with a limited shrub component, to support semi-arid reclamation, erosion control, and long-term cover stabilization.

The selected species are consistent with regional revegetation guidance that favors locally appropriate native seed sources for disturbed lands in New Mexico and with reclamation literature identifying Indian ricegrass as useful for erosion control and reclamation in arid and semi-arid areas receiving approximately 8 to 14 inches of annual precipitation. Blue grama is also widely used for rangeland improvement, mine-spoil reclamation, and roadside stabilization in the semi-arid Southwest. The total application rate of 9.0 pounds pure live seed per acre is within the range used for final mine reclamation seed mixes in New Mexico and should be adjusted, if necessary, based on seed availability, purity, germination, and agency-approved substitutions before construction.

Seed will be applied using standard mine reclamation equipment, including tracked or wheeled tractors, rangeland seed drills, and mulch spreaders where slopes and access allow. On areas steeper than 3H:1V or where equipment access is limited, hand broadcasting, chain seeding, hydroseeding, or comparable approved methods may be used. Seed shall be certified weed-free, applied on a pure-live-seed basis, and placed during an appropriate seasonal window for native species establishment. Mulch, tackifier, or temporary stabilization may be used where needed to protect seeded areas from wind and water erosion during establishment.

**Table 4-111 Proposed Seed Mix and Application Rates**

| **Common Name** | **Scientific Name** | **Lbs PLS/Acre** |
|---|---|---|
| Blue grama | *Bouteloua gracilis* | 1.5 |
| Indian ricegrass | *Achnatherum hymenoides* | 2.0 |
| Galleta | *Pleuraphis jamesii* | 1.5 |
| Fourwing saltbush | *Atriplex canescens* | 1.0 |
| Black grama | *Bouteloua eriopoda* | 1.0 |
| Sideoats grama | *Bouteloua curtipendula* | 1.5 |
| Prairie junegrass | *Koeleria macrantha* | 0.5 |
| **Total** | | **9.0** |

The seed mix shown in Table 4-11 is appropriate for inclusion in this report because revegetation is a functional component of the final cover system. Establishing a stable native plant community will reduce wind erosion, increase surface roughness, support evapotranspiration from the on-site soil cover, and limit the establishment of undesirable deep-rooted woody species. Final seed procurement should prioritize locally adapted or regionally appropriate native seed lots, and any

substitutions should maintain the same functional objectives of drought tolerance, erosion resistance, shallow rooting, and compatibility with the engineered cover.

## 4.13 Material Placement

Materials requiring permanent containment will be transported to the expanded disposal cell and placed under controlled construction procedures consistent with applicable federal and state requirements, including 40 CFR Part 192, 10 CFR Part 40 Appendix A, and project-specific reclamation specifications. The placement program is intended to maintain waste isolation, minimize voids, control long-term settlement, and preserve the final cover system. Materials managed under this section include:

- Contaminated soils requiring permanent containment;
- Facility debris and non-salvageable structures;
- Dismantled equipment and appurtenances; and
- Other approved closure materials designated for placement in the expanded disposal cell.

Before placement, structural materials and equipment designated for disposal will be prepared to promote safe handling, dense placement, and long-term settlement control. Preparation requirements include:

- Cut, dismantle, crush, or reduce materials to manageable dimensions;
- Stage and compact compressible debris in approved areas before incorporation into disposal cell fill;
- Fill pipes, conduits, tanks, vessels, and similar hollow items with suitable clean earthen material when they cannot be adequately crushed; and
- Place irregular or oversized components so surrounding soil can be compacted against them to minimize bridging, unsupported voids, and future differential settlement.

Disposal cell fill will be placed in controlled lifts to achieve the specified density and provide a stable foundation for subsequent waste placement and final cover construction. Unless otherwise approved by the Engineer, placement requirements include:

- Loose lift thickness not exceeding 12 inches;
- Compaction with suitable construction equipment until the specified density is achieved;
- Minimum compaction of 90 percent of the maximum dry density determined in accordance with ASTM D1557, unless material-specific specifications require otherwise;
- Field density testing at a minimum frequency of one test per 2,500 square feet per lift; and
- Reworking and retesting of nonconforming areas until the compaction requirement is met.

Co-placement of diesel-impacted soils with radiologically impacted materials is addressed in the EA regulatory evaluation completed in March 2026 (and is provided in Appendix J). The evaluation concluded that co-placement within the engineered disposal cell is permissible when

diesel-impacted soils are confirmed to be non-hazardous and managed under the controls listed below. Approximately 7,400 cubic yards of diesel-impacted soil have been identified in the North Controlled Area, where total petroleum hydrocarbon diesel range organics concentrations exceed the NMED industrial soil screening level within a discrete release area.

The diesel-impacted soils are not classified as hazardous waste under RCRA because TPH-DRO is not listed hazardous waste and the soils are not expected to exhibit hazardous characteristics, including ignitability, corrosivity, reactivity, or toxicity. The diesel release area does not coincide with the primary radiological hotspots, and areas where diesel and radiological impacts co-occur contain diesel concentrations below the applicable NMED screening level. Therefore, these materials do not constitute mixed waste under RCRA and the Atomic Energy Act.

Groundwater protection is provided by the engineered containment system and the substantial vertical separation between the disposal cell base and the groundwater table, which is approximately 70 to 95 feet below ground surface near the cell. The liner system, engineered cover, and long-term monitoring program provide isolation of both radiologically impacted materials and diesel-impacted soils. Published compatibility information also indicates that the HDPE liner system is suitable for contact with weathered petroleum hydrocarbons at the concentrations expected in the identified soils.

Implementation controls for diesel-impacted soils will provide traceability, confirm non-hazardous classification, and maintain compliance with the regulatory basis for co-placement. The principal controls include:

- Segregation of diesel-impacted soils during excavation and staging.
- Staging on an impervious surface before disposal cell placement.
- Confirmation sampling to verify non-hazardous classification.
- Separate management of any free-phase product, if encountered.
- Documentation of the final location and depth of diesel-impacted soils placed within the cell.

The co-placement approach reduces long-term environmental risk by consolidating contaminated materials within a single engineered containment system rather than creating a separate disposal location. Centralized placement also improves long-term inspection, monitoring, and institutional control of the affected materials and is consistent with the regulatory framework governing uranium mine reclamation in New Mexico.

During material handling, transport, staging, and placement, dust-control best management practices will be implemented in accordance with applicable EPA, state, and project-specific uranium mine reclamation requirements to protect workers and minimize fugitive dust emissions; these measures will include water application as needed, controlled vehicle speeds, limited drop heights during loading and placement, prompt covering or stabilization of disturbed material, and work stoppage or modified operations when wind conditions could cause unacceptable dust generation.

# 5.0 CONCLUSIONS

## 5.1 General

This report presents the design basis and performance analyses for the engineered cover system proposed for the expanded disposal cell at the Mt. Taylor Uranium Mine, Cibola County, New Mexico (EA Project No. 111360). The cover system is designed as a passive store-and-release (SAR) evapotranspiration barrier consistent with the performance requirements of 40 CFR Part 192, 10 CFR Part 40 Appendix A Criterion 6, and the New Mexico Copper Rule (20.6.7.33 NMAC), as a relevant state performance benchmark for store-and-release cover behavior. The analyses address interconnected performance requirements including frost protection, radon attenuation, biointrusion resistance, infiltration control, store-and-release capacity, slope stability, surface-water management, erosion protection, borrow-source suitability, revegetation, and material placement controls. The following subsections summarize the principal findings and regulatory compliance determinations for the analysis areas presented in Section 4.

## 5.2 Cover System Configuration

The proposed cover system consists of three layers totaling 52 inches (4.33 feet) of engineered material placed over the consolidated waste mass. From top to bottom, the layers are a 12-inch rock mulch admixture (30 percent AASHTO No. 1 gravel and 70 percent on-site soil cover material by volume), a 28-inch compacted on-site soil cover layer, and a 12-inch compacted clay radon barrier. The compacted clay barrier is the primary radon-attenuation and infiltration-control layer. Section 4.6 reports a design saturated hydraulic conductivity of $7.6\times10^{-6}$ cm/s for the compacted clay barrier, and Section 5.8 should therefore rely on that value unless the final design specification is revised. The on-site soil cover layer provides the design frost-depth protection above the clay barrier and the soil moisture storage capacity required for the store-and-release evaluation. The rock mulch layer controls surface water and wind erosion and provides a physical deterrent to burrowing. The layered configuration is evaluated in Section 4.2 of this report.

## 5.3 Frost Depth and Thermal Protection

Frost depth was computed using the Modified Berggren method, which accounts for finite soil heat capacity, differing frozen and unfrozen thermal properties, and non-zero initial soil temperature through a correction coefficient. The design-basis air freezing index is 927.5 degree-days for the 200-year return period, and the resulting design frost depth is approximately 28 inches. The 28-inch on-site soil cover layer therefore provides the required thermal buffer above the compacted clay radon barrier. The clay radon barrier remains at or below the base of the frost-active zone under design conditions, limiting freeze-thaw degradation of the low-permeability layer over the design life. The frost depth analysis is presented in Section 4.3 and Appendix D.

## 5.4 Radon Attenuation

Radon attenuation was evaluated using the one-dimensional steady-state diffusion model implemented in the Wise Uranium Project Uranium Mill Tailings Cover Calculator, following NRC Regulatory Guide 3.64 (NRC, 1989). The regulatory limit is 20 pCi/m²/s averaged over the disposal cell surface, per 40 CFR Part 192 and 10 CFR Part 40 Appendix A Criterion 6.

The design radium-226 (Ra-226) source term of 115 pCi/g is conservative relative to the arithmetic mean of 101.3 pCi/g derived from 124 survey locations across five source areas characterized by AVM Environmental Services, Inc. (2023). Materials from the Ore Pad Area, which exhibit the highest mean Ra-226 activity at 431.6 pCi/g, are designated for placement at the base of the disposal cell to minimize high-activity material near the cover interface. During placement, higher-activity radiological materials will be blended with lower-activity materials, where practical, to minimize elevated spot concentrations and reduce localized variability within the waste mass. The clay radon barrier was modeled with a long-term in-service moisture content of 15.1 percent (15-bar SWCC value), a dry density of 1.59 g/cm³, a porosity of 0.38, and a resulting radon diffusion coefficient of $4.62\times10^{-7}$ m²/s.

The model yields a bare-source surface flux of 42.10 pCi/m²/s in the absence of cover and a design surface flux of 13.99 pCi/m²/s at the top of the rock mulch layer. The three-layer cover system attenuates 66.77 percent of the bare-source flux, producing a design value that is 30 percent below the regulatory limit of 20 pCi/m²/s. The radon attenuation analysis is presented in Section 4.4.

## 5.5 Biointrusion

The cover system is designed to satisfy the biointrusion-related requirements of 10 CFR Part 40 Appendix A Criterion 6, which requires radiological hazard control for 1,000 years to the extent reasonably achievable, and in any case for at least 200 years. Current NRC and DOE guidance recognizes that shallow-rooted native vegetation can support SAR cover performance by removing stored soil moisture through transpiration. The primary biointrusion concern is therefore associated with deep-rooted woody plants and burrowing animals that could physically disturb or penetrate the compacted clay radon barrier.

Physical deterrents are provided at multiple levels. The 12-inch rock mulch surface layer presents a coarse, discontinuous substrate that resists burrowing and reduces the likelihood of direct animal disturbance. The 28-inch compacted on-site soil cover layer separates routine biological activity from the clay radon barrier while supporting the shallow-rooted native grass community specified in the revegetation plan. The compacted clay radon barrier is protected by the overlying 40 inches of cover material. Biointrusion controls will be supplemented by post-closure inspection and adaptive management for woody vegetation, burrowing activity, cracking, erosion, or localized cover damage. The biointrusion analysis is presented in Section 4.5.

## 5.6 Infiltration, Water Balance, and Copper Rule Compliance

The infiltration analysis is based on the 2018–2025 San Mateo on-site meteorological record, which yields a mean annual precipitation (MAP) of 10.01 in/yr and a Thornthwaite (1948) potential evapotranspiration (PET) of 26.45 in/yr. The resulting aridity index, expressed as PET/P = 2.64 in Section 4.6, confirms that the site climate is strongly water-limited, with evapotranspirative demand substantially exceeding available precipitation throughout most of the year.

Actual evapotranspiration (AET) was estimated using the Budyko (1948) method and accounts for 9.30 in/yr, or 92.9 percent of MAP. Surface runoff, estimated using the SCS Curve Number method with CN = 55 on a monthly time step, is 0.021 in/yr and is negligible because only peak monsoon months exceed the initial abstraction threshold of 1.64 inches. The resulting analytical water-balance estimate of percolation is 0.69 in/yr, representing a conservative upper bound of 6.9 percent of MAP. Two-dimensional transient seepage modeling using GeoStudio SEEP/W, which captures inter-annual soil moisture storage dynamics not reflected in the steady-state water balance, yields a design-basis percolation rate of 0.40 in/yr, or 4.0 percent of MAP. This value is adopted as the design basis.

Copper Rule compliance was evaluated by comparing the water storage capacity of the 28-inch on-site soil cover layer against the seasonal precipitation thresholds specified in 20.6.7.33 NMAC. Using the 2018–2025 San Mateo station record, winter precipitation from October through March totals 2.87 inches and summer precipitation from April through September totals 7.14 inches. The winter threshold governs, resulting in a required storage capacity of 2.73 inches. The nominal available water holding capacity (AWHC) of the on-site soil cover (CL-ML), derived from laboratory Soil Water Characteristic Curve testing, is 0.10 in/in. The 28-inch layer provides 2.80 inches of storage, exceeding the 2.73-inch requirement by 0.07 inch. Total cover thickness of 52 inches also exceeds the Copper Rule minimum of 36 inches. The infiltration and Copper Rule analysis is presented in Section 4.6.

## 5.7 Surface Water Hydrology and Erosion Protection

Erosion protection design follows the procedures of NUREG-1623 (NRC, 2002) and NUREG/CR-4620 (Nelson et al., 1986). The design storm for cover rock mulch sizing is the Probable Maximum Precipitation (PMP), developed using the HMR-49 procedures documented in Appendix I for the Mt. Taylor site. For the disposal cell cover, the short-duration PMP governs rock mulch erosion checks because cover-slope times of concentration are short. For the diversion channel, the PMP-derived Probable Maximum Flood (PMF) governs watershed response and channel lining design. The 100-year, 24-hour precipitation depth documented in Appendix D is substantially less severe than the PMP condition and therefore does not govern erosion-protection design.

Peak unit discharges were computed using the Rational Method with a runoff coefficient of 0.80 and a flow concentration factor of 3.0 per NUREG-1623. Rock mulch $D_{50}$ requirements were evaluated using the Abt-Johnson method. The AASHTO No. 1 gravel component of the admixture, with nominal $D_{50}$ = 2.20 inches, provides a factor of safety of 2.65 at 50-foot slope segments, declining to 1.08 at 250 feet and 0.97 at 300 feet. A maximum interceptor berm or grade-break spacing of 250 feet is adopted as the design standard, maintaining a factor of safety greater than 1.0 for unsupported slope runs under the Appendix I design assumptions.

Filter compatibility of the rock mulch admixture was evaluated using the Leps (1973) interstitial velocity criterion. A conservative gravel-only analysis using $D_{50}$ = 2.20 inches yields an interstitial velocity of 1.99 ft/s, which exceeds the 1.0 ft/s threshold for open-graded rockfill. A refined analysis using the governing blended admixture $D_{50}$ of 0.0106 inch reflects the 70 percent on-site soil cover fines that fill and effectively reduce the inter-gravel void space, yielding an interstitial velocity of 0.004 ft/s, well below the 0.5 ft/s no-filter threshold. The Terzaghi (1943) filter-

compatibility criterion is independently confirmed, with the blended $D_{15}$ to subgrade $D_{85}$ ratio equal to 0.045, which is less than the allowable value of 5.0. A separate filter layer beneath the rock mulch cover is therefore not required. Shield's incipient motion and Pemberton-Lara (1984) scour-depth analyses confirm that the armor layer develops within the 12-inch admixture depth during the design storm before scour reaches the underlying on-site soil cover. The computed scour depth is approximately 10.3 inches, less than the 12-inch admixture thickness. Wind erosion is evaluated using WEPS and the EPA benchmark of less than 2 tons/acre/year, as described in Section 4.9.4. The surface water hydrology and erosion protection analysis is presented in Section 4.9 and Appendix I.

## 5.8 Slope Stability, Borrow Sources, Revegetation, and Material Placement

The slope stability analysis presented in Section 4.8 demonstrates that the combined expanded disposal cell configuration with 5H:1V final cover slopes satisfies the applicable static and pseudo-static stability criteria for the analyzed section. The static factor of safety exceeds the target value of 1.5, and the pseudo-static factor of safety using a horizontal seismic coefficient of 0.14 exceeds the target value of 1.1. Borrow-source evaluations in Sections 4.10 and 4.11 indicate that suitable clay and on-site soil cover materials are available onsite, subject to field verification, selective excavation, laboratory confirmation, and construction quality assurance. The revegetation plan in Section 4.12 supports erosion control, evapotranspiration, and long-term cover stabilization using native, drought-adapted species. Material placement controls in Section 4.13 address waste consolidation, compaction, settlement control, diesel-impacted soil co-placement, dust control, and traceability during construction.

## 5.9 Regulatory Compliance Summary

The performance analyses summarized in Sections 5.2 through 5.8 collectively demonstrate that the proposed 52-inch three-layer engineered cover system satisfies applicable regulatory performance requirements. The clay radon barrier remains below the frost-active zone, preserving its hydraulic integrity over the design life. The design surface radon flux of 13.99 pCi/m²/s is 30 percent below the 40 CFR Part 192 limit of 20 pCi/m²/s. The multi-layer physical configuration, in combination with the targeted revegetation plan and post-closure stewardship, limits biointrusion risk to manageable levels consistent with NRC guidance. The design-basis percolation rate of 0.40 in/yr, or 4.0 percent of MAP, confirms effective hydraulic isolation of the waste mass, and the Copper Rule storage benchmark of 2.73 inches is satisfied with a margin of 0.07 inch under nominal AWHC conditions. The rock mulch admixture with a 250-foot maximum berm spacing provides adequate resistance to PMP-driven surface erosion and functions as a self-filtering medium without a separate filter layer. The slope stability, borrow-source, revegetation, and material placement evaluations provide additional support for constructability and long-term cover performance. The cover system design is considered to satisfy the long-term performance requirements of 40 CFR Part 192, 10 CFR Part 40 Appendix A Criterion 6, and the applicable state review framework and is recommended for submittal to the NRC and NMED for review and approval.

5.0 Atterberg Limits

6.0 Flexible Wall Permeability

7.0 Soil Water Characteristic Curve

8.0 Standard Proctor Compaction

9.0 Consolidated Undrained Triaxial Shear

# 1.0 Summary

This report presents the results of laboratory testing conducted on soil samples provided by Engineering Analytics of Fort Collins, Colorado. The sample selection and testing parameters were designated by personnel from Engineering Analytics. All laboratory analyses were performed by Engineering Analytics under the direct supervision of a Professional Engineer licensed in the State of Colorado.

The testing procedures adhered to the standards outlined by the American Society of Testing and Materials (ASTM). Where ASTM standards were not applicable, established industry standards were employed. Any deviations from standard procedures are explicitly noted within this report the table below lists ASTM procedures used in this investigation. The results of the laboratory tests, including relevant graphical representations, are presented in the following sections.

| Test Performed | ASTM Test Method | No. of Tests Performed |
|---|---|---|
| Moisture Determination | D2216 | 48 |
| Percent Passing No. 200 | D1140 | 48 |
| Atterberg Limits | D4318 | 48 |
| Flexible Wall Permeability | D5084 | 2 |
| Soil Water Characteristic Curve | D6836 | 7 |
| Standard Proctor Compaction | D698 | 8 |
| Consolidated Undrained Triaxial Shear | D4767 | 1 |

MCS = Modified California Sample, BKT = Bucket

## 3.0 Moisture Content

The natural moisture content of 48 soil samples was determined in accordance with ASTM D2216, "Standard Test Methods for Laboratory Determination of Water (Moisture) Content of Soil and Rock by Mass."

This test yields the gravimetric moisture content, expressed as a percentage, which represents the ratio of the mass of water to the mass of dry soil within the sample.

A summary of the natural moisture content results are presented in Section 2.0 of this report.

# 4.0 Percent Passing No. 200

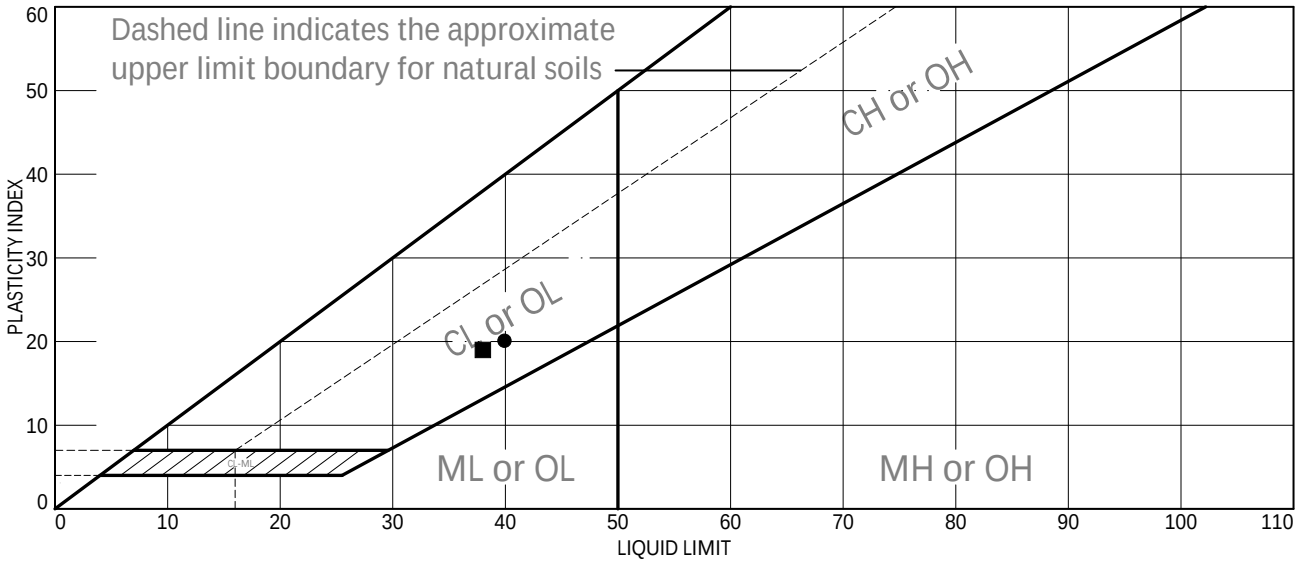
A selection of 48 soil samples was tested in general accordance with ASTM D1140, "Standard Test Methods for Determining the Amount of Material Finer than 75-µm (No. 200) Sieve in Soils by Washing."

- A selection of soil samples was tested in general accordance with ASTM D1140, "Standard Test Methods for Determining the Amount of Material Finer than 75-µm (No. 200) Sieve in Soils by Washing."
- The testing procedure involved oven-drying the samples, recording their initial dry weight, and then washing them through a 75-µm (No. 200) sieve.
- The material retained on the sieve was recovered, oven-dried, and weighed.
- The percentage of material passing the No. 200 sieve was calculated using the initial total dry weight of the sample and the dry weight of the material retained on the sieve.

A summary of the percent finer than No. 200 sieve results is presented in Section 2.0 of this report.

# 5.0 Atterberg Limits

The Atterberg Limits, specifically the liquid limit (LL) and plastic limit (PL), were determined on 48 soil samples in accordance with ASTM D4318, "Standard Test Methods for Liquid Limit, Plastic Limit, and Plasticity Index of Soils."



- Sample Preparation:
    - The soil sample is processed to pass the 0.425 mm (No. 40) sieve.
    - A representative portion of this fine-grained material is used for the tests.
- Liquid Limit (LL):
    - A soil paste is prepared with distilled water.
    - The paste is placed in a Casagrande cup, and a groove is made in the soil.
    - The cup is repeatedly dropped from a specified height.
    - The liquid limit is determined as the moisture content at which the groove closes over a distance of 12.7 mm (0.5 inches) after 25 blows.
- Plastic Limit (PL):
    - A soil thread is rolled out on a flat surface.
    - The plastic limit is determined as the moisture content at which the soil thread crumbles when rolled to a diameter of 3.2 mm (1/8 inch).
- Plasticity Index (PI):
    - The plasticity index is calculated by subtracting the plastic limit from the liquid limit (PI = LL - PL).

A summary of the Atterberg Limits test results is presented in Section 2.0 of this report.

A graph depicting the Plasticity Index versus the Liquid Limit is included on the following pages.

# 6.0 Flexible Wall Permeability

The hydraulic conductivity (coefficient of permeability) of saturated porous material was determined on 2 soil samples using a flexible wall permeameter in accordance with ASTM D5084, "Standard Test Methods for Measurement of Hydraulic Conductivity of Saturated Porous Materials Using a Flexible Wall[1] Permeameter (Method C: Falling Head Test)."

- Soil samples were trimmed, encased within a flexible rubber membrane, and placed within a triaxial test cell.
- An initial effective stress of 1-3 psi was applied to each sample to facilitate saturation.
- Following saturation, each sample was consolidated to the effective stress specified by the project engineer.
- After a 24-hour consolidation period, a hydraulic gradient was established by applying differential pressures to the top and bottom of the samples. The magnitude of the gradient was determined based on the soil classification.
- The outflow of water from the top of the sample was measured at predetermined time intervals to determine the flow rate and, subsequently, the hydraulic conductivity.

The results of the hydraulic conductivity are presented on the following pages

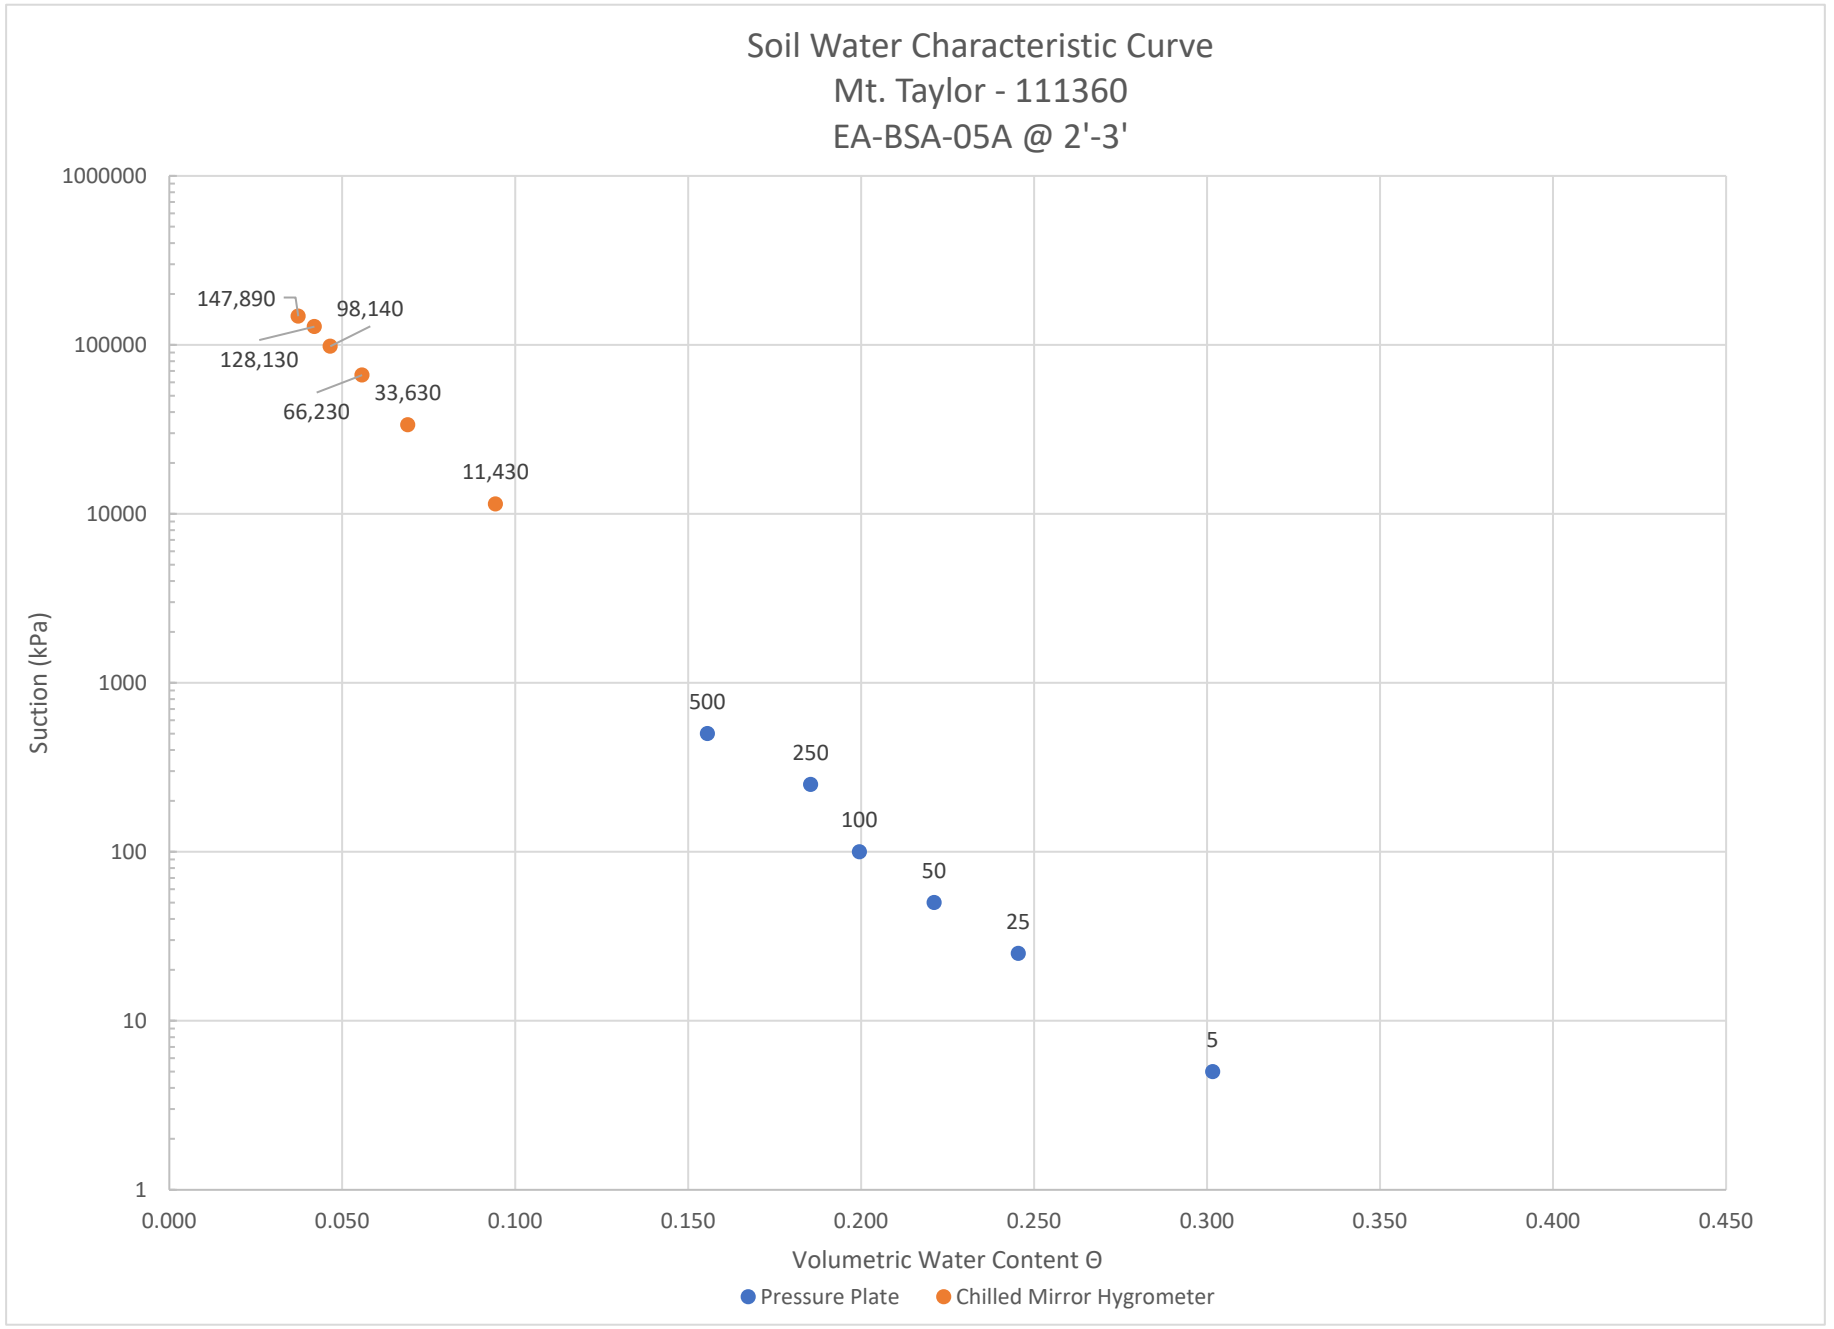
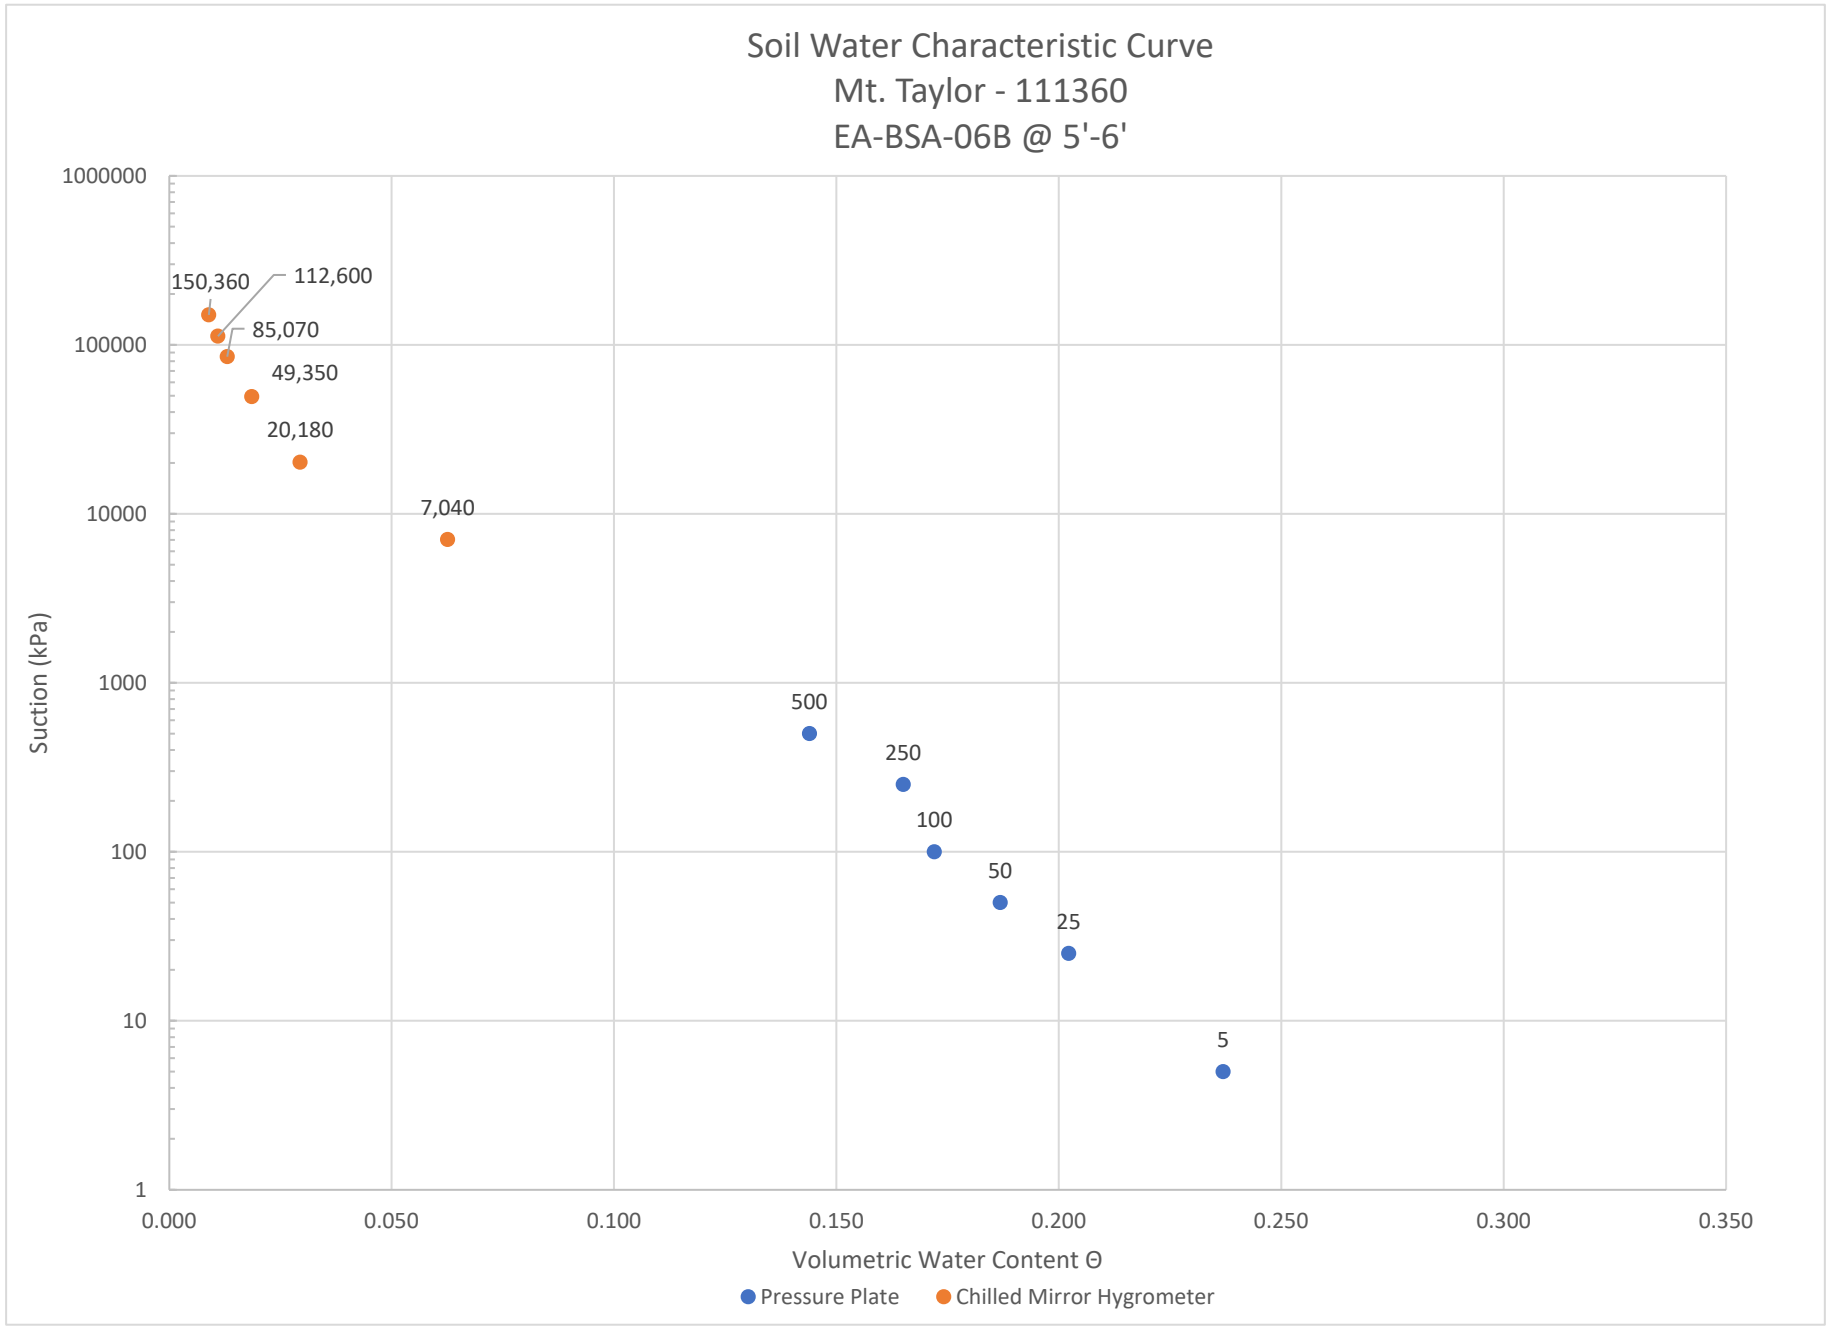
# 7.0 Soil Water Characteristic Curve

The moisture-retention curve (also known as the soil-water characteristic curve) was determined on 7 soil samples in accordance with ASTM D6836, "Standard Test Methods for Determination of the Soil Water Characteristic Curve for Soil and Rock by the Pressure Plate Method." This test establishes the relationship between the water content of a soil and the applied suction or negative matric potential (soil water potential).

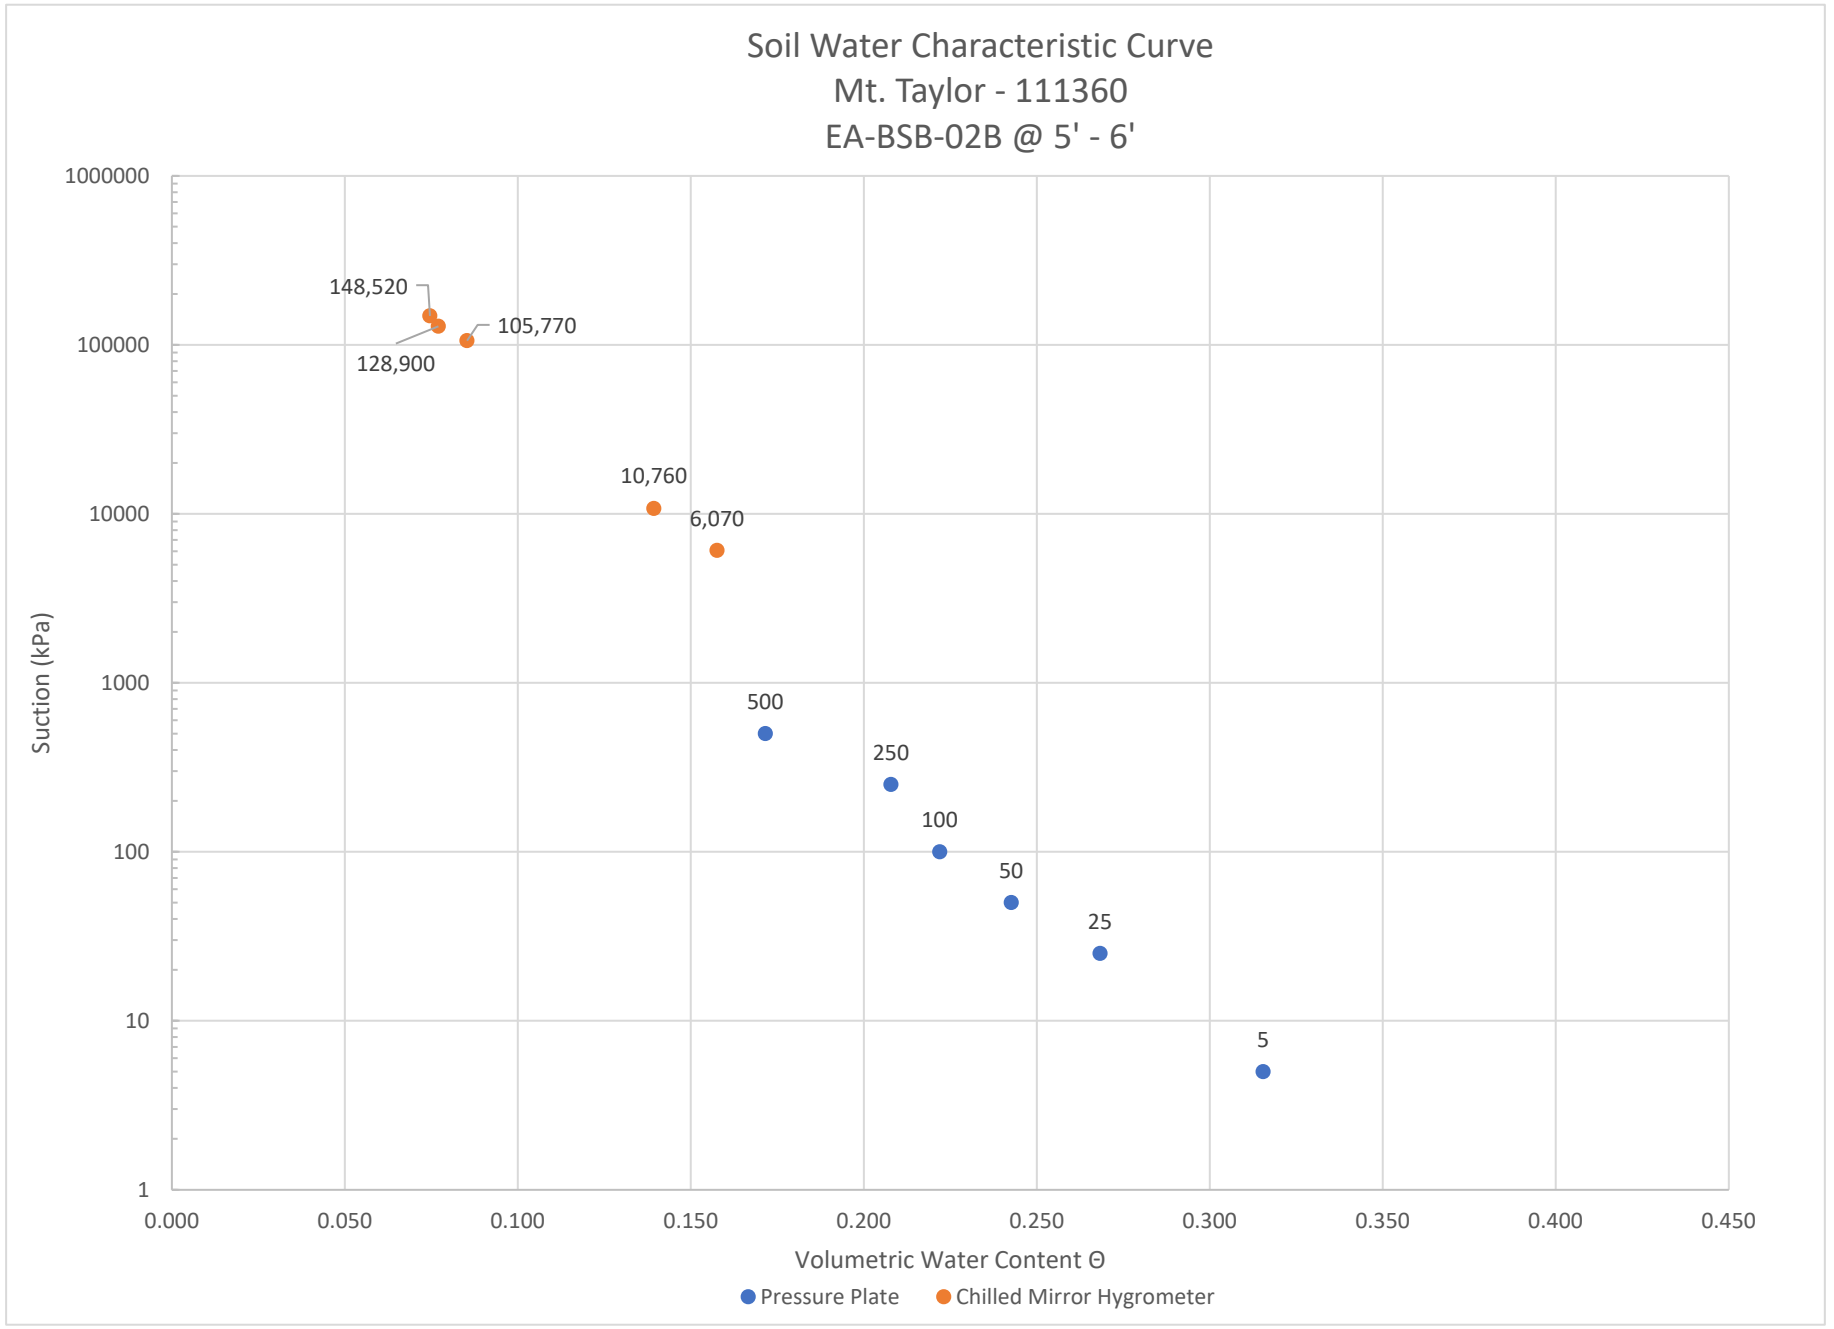
To create a full-range curve, a combination of two methods was employed:



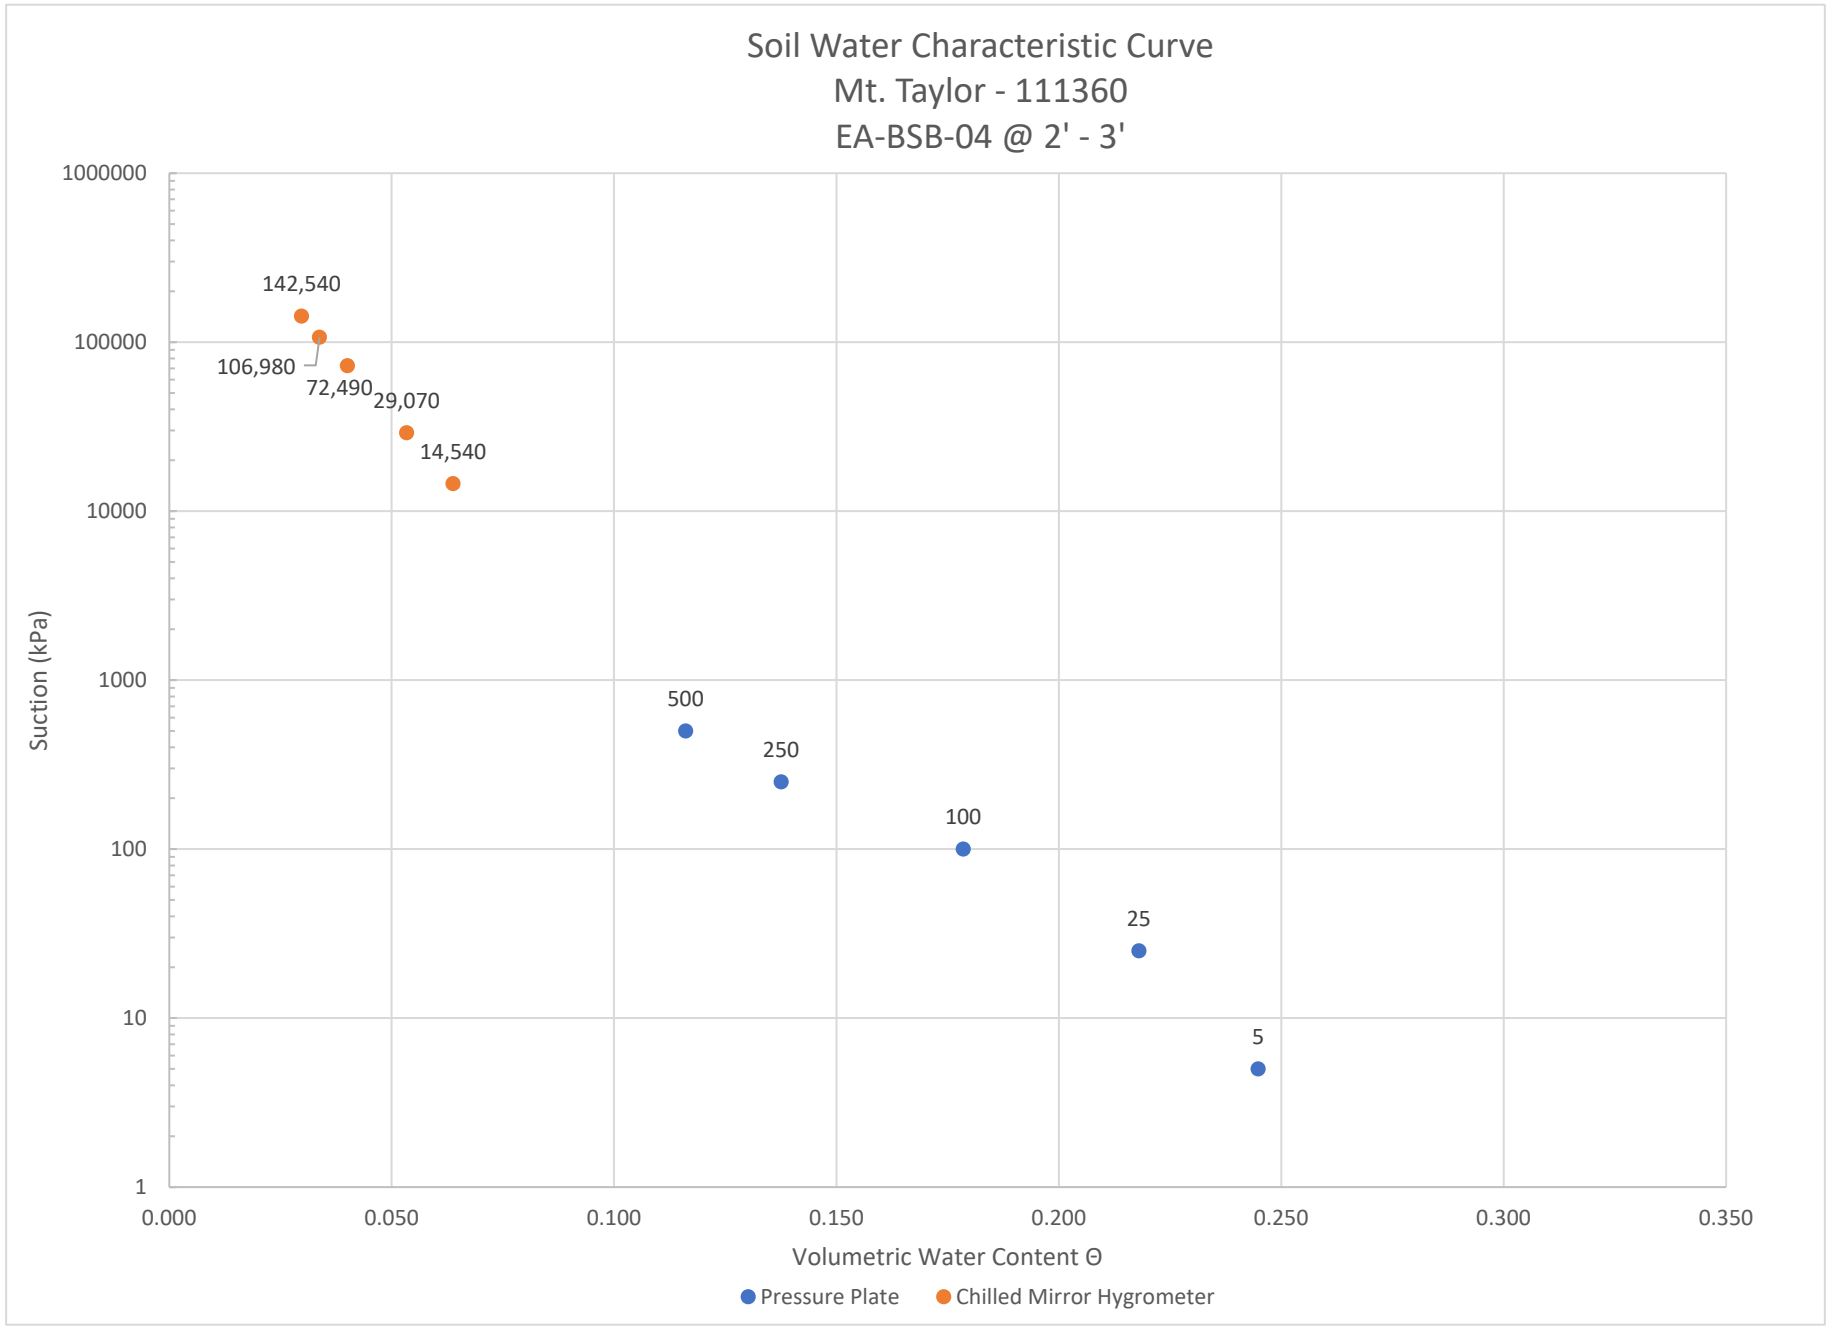
- Low Suction Range (Method C - Pressure Plate): Used to determine the water content at low suctions (0 kPa to 500 kPa).
- High Suction Range (Method D - Chilled Mirror Hygrometer): Used to determine the water content at high suctions (500 kPa to 250,000 kPa or more).



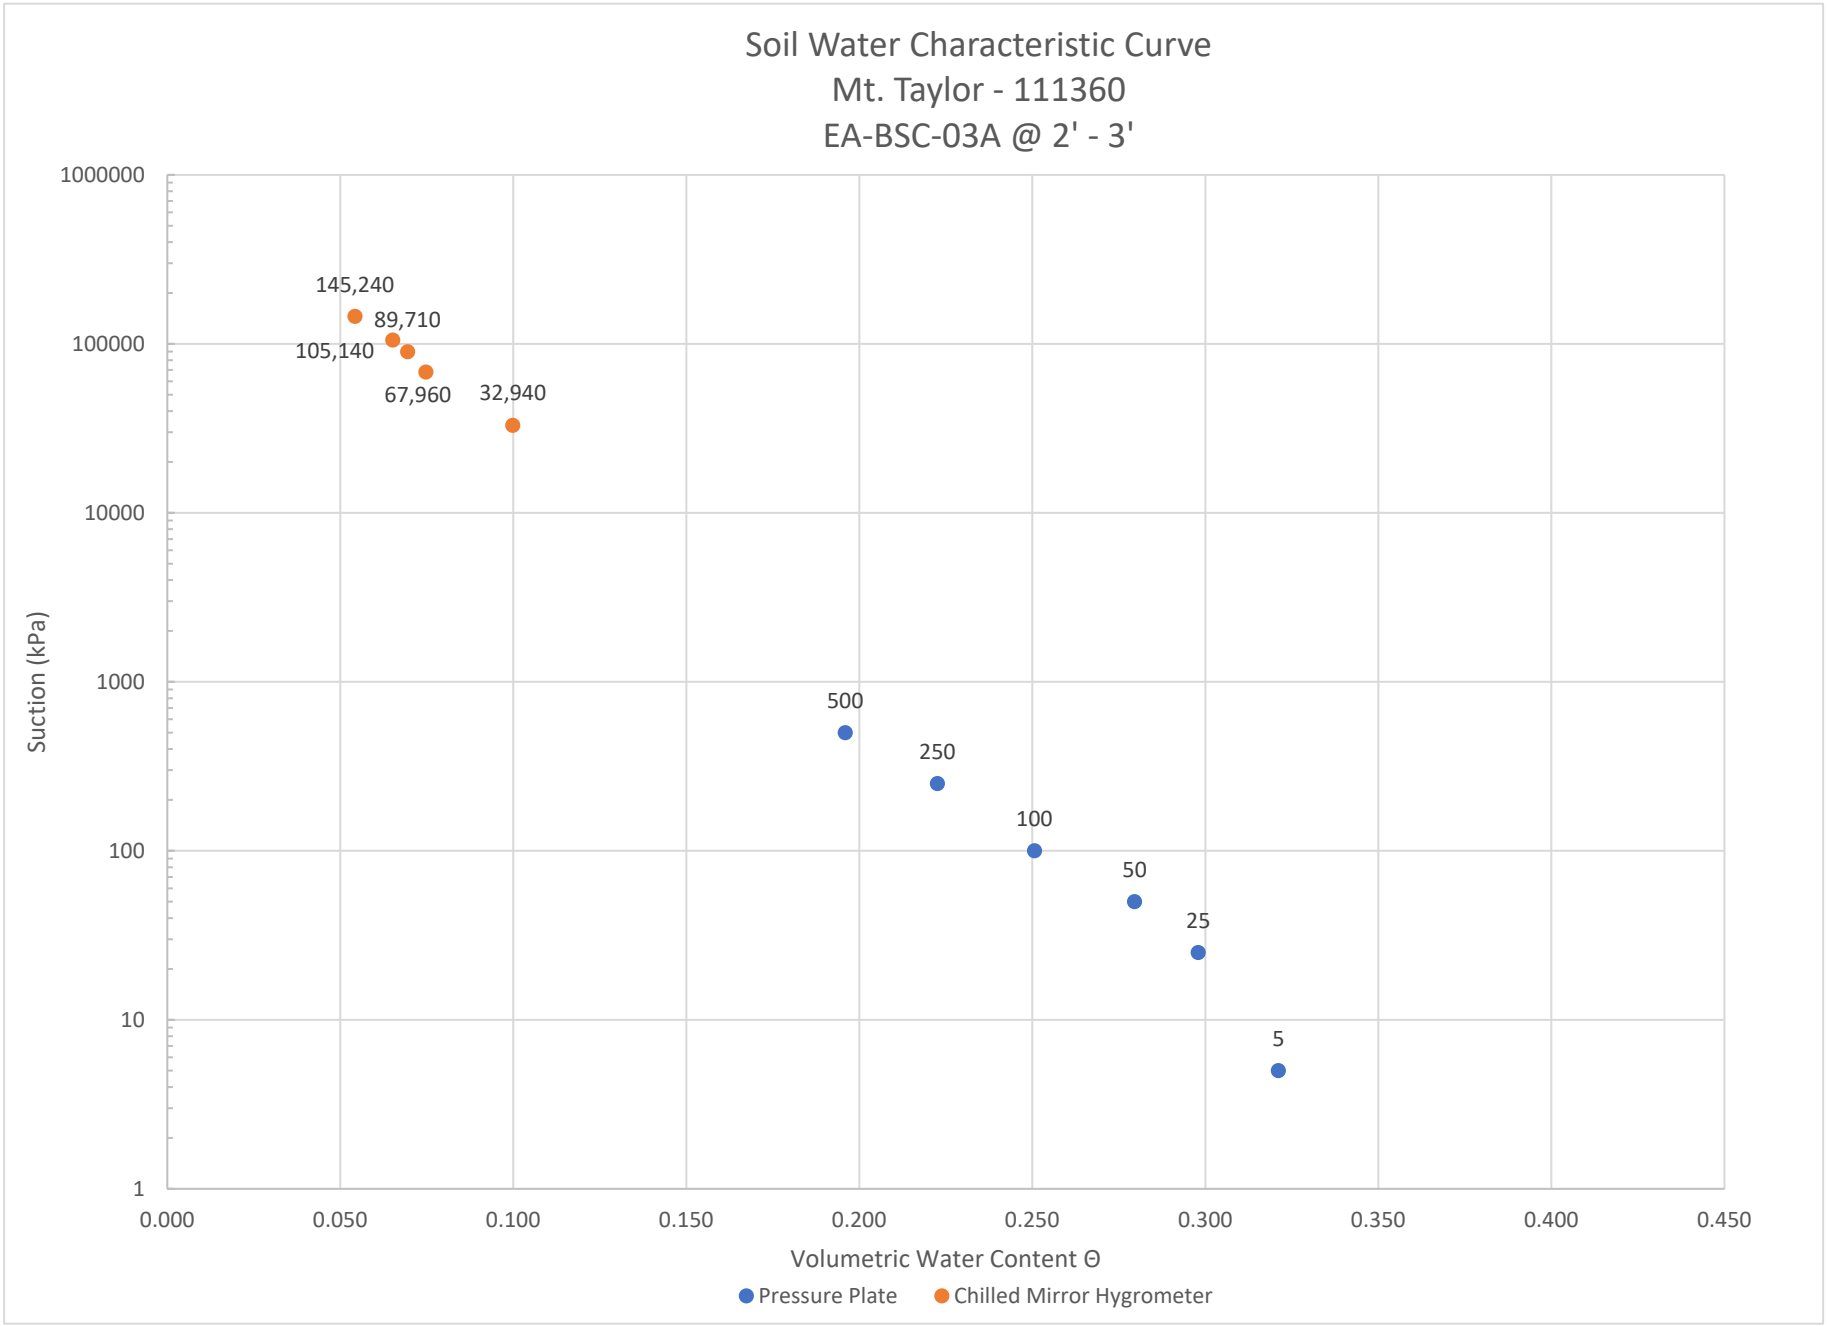
Combined Test Procedure



1. Sample Preparation (Method C): Representative soil specimens were prepared and placed on ceramic plates of appropriate air-entry values within a pressure chamber.
2. Saturation: The specimens were saturated by submerging them in water, allowing them to reach equilibrium.
3. Low Suction Application (Method C): The pressure chamber was subjected to a series of low, incremental air pressures (suctions), typically up to 1500 kPa. At each pressure step, the system was allowed to reach hydraulic equilibrium (i.e., water stopped flowing out of the samples). The water outflow was measured and recorded.
4. High Suction Application (Method D): After the final low-suction step, or on a separate subset of samples, the soil was tested using the Chilled Mirror Hygrometer technique.
    - A small, representative portion of the soil was placed in the hygrometer's sample chamber.
    - The instrument measured the relative humidity in equilibrium with the soil water potential (suction) above the sample.
    - This measurement was taken by chilling a mirror surface until dew condensation occurred. The measured dew point temperature was used to calculate the corresponding high soil suction.
5. Moisture Content Determination: For both methods, the water content corresponding to each suction step was determined, by determining the gravimetric moisture content of the tested specimen.



By combining the data from the Pressure Plate (low suction) and the Chilled Mirror Hygrometer (high suction), a complete moisture-retention curve was generated, spanning the full range of suction required for engineering analysis.



The results of the Soil Water Characteristic Curves are presented on the following pages.

# 8.0 Standard Proctor Compaction

Standard Proctor Compaction tests were performed on 8 selected soil samples in accordance with ASTM D698, “Standard Test Methods for Laboratory Compaction Characteristics of Soil Using Standard Effort.”

- For each test, soil at a predetermined moisture content was placed in three equal layers into a cylindrical mold of specified dimensions. Each layer was compacted by 25 blows from a 5.5-pound (2.49 kg) hammer dropped from a height of 12 inches (305 mm) for Methods A and B of the standard. For Method C, a larger mold and 56 blows per layer were used. The specific method employed is noted in the results section.
- Following compaction, the wet unit weight of the soil in the mold was determined by measuring the mass of the compacted soil and the known volume of the mold.
- The moisture content of a representative portion of the compacted soil was determined, and the dry unit weight was subsequently calculated.
- This procedure was repeated for each soil sample with four or more different moisture contents to establish the moisture-density relationship (compaction curve) for the soil.

Graphs illustrating the moisture-density relationships (Proctor curves) for each tested soil sample are shown on the following pages.

# 9.0 Consolidated Undrained Triaxial Shear

Consolidated undrained (CU) triaxial shear tests were performed on 1 soil samples in accordance with ASTM D4767, "Standard Test Method for Consolidated Undrained Triaxial Compression Test for Cohesive Soils."

- Soil samples were trimmed, encased in a rubber membrane, and installed in the triaxial test cell.
- An initial effective stress of 1-3 psi was applied to facilitate saturation.
- Specimens were saturated to ≥ 95%.
- Following saturation, samples tested using the three-load method were consolidated to the effective stress specified by the project engineer. Samples tested using the three-stage method were consolidated to the effective stresses designated prior to each stage of testing.
- During the consolidation phase, drainage was permitted, allowing for volume changes.
- After a 24-hour consolidation period, the triaxial load cell was engaged, drainage was closed, and axial loading was initiated.
- Axial load, deformation, and pore-water pressure were measured to determine total stresses and axial compression.
- Each sample was sheared, and axial strain was recorded.
- Strength envelopes (total stress Mohr circles) were developed based on the test data.
- Strength envelopes were determined using either the three-load or three-stage method, as specified by the project engineer.
    - The three-load method utilizes data from three distinct samples, each consolidated under a different effective stress.
    - The three-stage method utilizes one sample, which is consolidated to differing effective stresses for each stage of the test.

The results of the CU tests are presented on the following pages.

| Sample No. | | 1 | 2 | 3 |

# 1.0 INTRODUCTION

Engineering Analytics, Inc. (EA) has prepared this report to present the results of a seismic hazard analysis conducted for the Mt. Taylor Uranium Mine (Facility). This seismic hazard analysis has been prepared to characterize the peak horizontal ground acceleration (PGA) for use in stability analyses for the Facility. The seismic hazard was determined for the 10,000-year return period.

The Mt Taylor Uranium Mine is located just northeast of the town of San Mateo in Cibola County, New Mexico. The site is shown on Figure 1-1. For the purposes of these analyses, EA used a central location with coordinates of 35.3409°N latitude and 107.6353°W longitude.

# 2.0 GEOLOGIC SETTING

## 2.1 Regional Physiographic and Tectonic Setting

The Facility is located within the Colorado Plateau physiographic province in northwestern New Mexico. The Colorado Plateau is a broad, roughly circular region of relative structural stability within a more structurally active region of disturbed mountain systems. Broad basins and uplifts, monoclines, and belts of anticlines and synclines are characteristic of the plateau (Kelley, 1979). Igneous intrusions have formed several mountains. However, most of the topographic relief in the Colorado Plateau is the result of erosion of deep canyons rather than upstanding mountain ranges (Thornbury, 1965). According to the New Mexico Bureau of Geology and Mineral Resources (2025):

> *The Colorado Plateau in New Mexico includes the San Juan Basin, a major source of oil, gas, coal, and uranium for our state. The northwest-trending Zuni Mountains form the southwestern margin of the San Juan Basin. Both the San Juan Basin and the Zuni Mountains are broad downwarps and upwarps that formed during regional-scale compression about 75 million years ago during the Laramide orogeny (e.g., Cather, 2004). The southeast margin of the Colorado Plateau is covered by <5 million year-old volcanic rocks that erupted along the Jemez lineament, a northeast-trending zone of weakness that likely developed about 1.6 billion years ago as the North American continent was forming.*

The site is located at the base of the Mt Taylor Volcanic Field. Mount Taylor is an extinct composite stratovolcano that is part of the greater Mount Taylor–Mesa Chivato volcanic field (Hunt, 1938; Crumpler, 1980a, b). According to the New Mexico Bureau of Geology and Mineral Resources (2025):

> *Mount Taylor volcano, a prominent landmark that can be seen on the skyline west of Albuquerque, is located about 15 miles northwest of the town of Grants, New Mexico. Mount Taylor Peak, at an elevation of 11,301 feet, stands approximately one mile above the Rio San Jose 12 miles to the south (Hunt, 1938). Mount Taylor volcano is part of a larger, northeast-trending volcanic field that includes Mesa Chivato, a broad plateau located northeast of the cone, and Grants Ridge (Keating and Valentine, 1998; WoldeGabriel et al., 1999), located southwest of the cone. Basalt that caps Mesa Chivato and other mesas surrounding Mount Taylor makes up about 80% of the volume of the volcanic field (Perry et al., 1990). The Mount Taylor volcanic field lies on the southern flank of the San Juan Basin on the Colorado Plateau and straddles the extensional transition zone between the Colorado Plateau and the Rio Grande rift. The Mount Taylor volcanic field is considered to be part of the Jemez Lineament, a zone of young (< 5 million years old) volcanism aligned along an ancient suture in the 1.7 to 1.6 billion year old Proterozoic basement (Mayo, 1958, Laughlin et al., 1976; Lipman and Moench, 1972; Perry et al., 1990).*

Seismicity in the Mt Taylor Volcanic Field is generally low and is linked to regional tectonic activity rather than active volcanism. This seismic activity is influenced by geological features such as the Jemez Lineament and the Rio Grande Rift (Goff et. al., 2021). The adjacent Rio Grande Rift physiographic province is characterized as having low to moderate seismic activity.

## 2.2 Site Geology

The geologic map by McCraw et. al. (2009) indicates that the Facility is underlain by Quaternary-aged stream and valley slope alluvium overlying the Cretaceous-aged Menefee Formation. The alluvium is described as unconsolidated to partly consolidated, well-sorted, fine-grained sand, silty sand, and clay with a thickness 1 to 3 meters (McCraw et. al., 2009). The Menefee Formation is described as interbedded shales, siltstones, fine to medium grained sandstones, mudstones, and thin coals that generally form low-relief topography or forms landslides around the margins of the basalt-capped La Jara Mesa. The top of the unit is not exposed, but a minimum thickness is at least 90 meters (McCraw et. al., 2009).

## 3.0 SEISMICITY

NRC NUREG-6372 recommends that seismic sources within 300 kilometers be characterized for a site. The publication states that the distance for detailed source characterization for a site that contains a fault within 50 kilometers of the site is 100 kilometers. Therefore, this seismic hazard analysis for the Facility included a review of historic earthquakes which have occurred within 300 kilometers of the Facility and detailed review of the earthquakes within 100 kilometers. This earthquake record, which contains earthquakes from 1568 to 2025, provides a general overview of the seismicity in the study area. Our final search and review of earthquake activity took place on August 27, 2025; therefore, any earthquakes occurring after this date are not included in the analysis.

Catalogs from the USGS NSHMP for 2023 for the Western United States (WUS) and Central and Eastern United States (CEUS) (Peterson et. al., 2023) were reviewed to compile information on the historic earthquakes. These catalogs, compiled by the USGS for their study, included removal of duplicate events as well as aftershocks and foreshocks related to the primary earthquake events in order to obtain a catalog of independent events (Mueller, 2019 and Llenos, 2023). EA used the catalogs declustered with Reasenberg (1985; r85). The database includes historic seismic events over the period from 1568 through 2022. The WUS catalog contained 40 earthquakes in the 300-kilometer study area and the CEUS catalog contained no earthquakes. The catalogs were supplemented with events occurring between January 2023 and August 2025 by searching the National Earthquake Information Center (NEIC) database, also maintained by the USGS. This supplemental search resulted in no additional earthquakes. The catalog searches were limited to events with moment magnitude (Mw) greater than or equal to 4.0. A total of 40 events are included in the record for the 300-kilometer search as shown on Figure 3-1 and tabulated in Appendix A.1.

The earthquakes generally have small magnitudes with only 5 of the earthquakes having a magnitude greater than 5.0. Figure 3-1 shows that many of the earthquakes occur in the more seismically active Rio Grande Rift area to the east of the Facility. The largest event is estimated in the WUS catalog to have an Mw of 5.9. This event occurred west of San Antonio, New Mexico on July 16, 1906. The epicenter is approximately 160 kilometers southeast of the Facility, within the Rio Grande Rift. The event closest to the Facility had an epicenter about 13 kilometers southwest of the Facility. This earthquake, which occurred on December 24, 1973, had an Mw of 4.08.

In addition to the evaluation of significant earthquakes (Mw>4) as described above, a search of low magnitude events (Mw>2.4) within 100 kilometers of the Facility was also conducted. These events are shown in Figure 3-2 and are tabulated in Appendix A.2. The figure shows that the earthquake activity within a 100-kilometer radius of the site is diffuse. The earthquake record contained 15 earthquakes from the WUS catalog and 9 earthquakes from the NEIC catalog, the majority of which are low magnitude. A review of the historic seismicity confirms that this area has seen fairly low seismic activity.

# 4.0 SEISMIC HAZARD ANALYSIS

Seismic hazard analyses are typically conducted using one of two methods: (1) deterministic analysis or (2) probabilistic analysis. A deterministic seismic hazard analysis (DSHA) estimates the maximum ground motion that could occur at a specific location considering specific earthquake sources. It does not take into account the likelihood of occurrence. A probabilistic seismic hazard analysis (PSHA) estimates the likelihood that various levels of ground motion will be exceeded at a specific location over a given time. Both analyses were conducted for this seismic study as discussed below. EA used the deterministic analyses to aid in the probabilistic analyses. The final recommended PGA for the Facility was derived using probabilistic analyses for the 10,000-year return period. The seismic sources and attenuation equations used for this seismic hazard analysis are also discussed below, followed by the results of the deterministic and probabilistic analyses.

## 4.1 Seismic Sources

### 4.1.1 Faults

The existence and location of faults with Quaternary displacement were primarily identified using the USGS Quaternary Fault and Fold database (USGS et. al., 2025). A "capable fault" is defined by the Nuclear Regulatory Commission (NRC) in 10 CFR Appendix A to Part 100 – Seismic and Geologic Siting Criteria for Nuclear Power Plants – as a fault that has exhibited one or more of the following characteristics:

1. *Movement at or near the ground surface at least once within the past 35,000 years or movement of a recurring nature within the past 500,000 years.*

2. *Macro-seismicity (magnitude 3.5 or greater) instrumentally determined with records of sufficient precision to demonstrate a direct relationship with the fault.*

3. *A structural relationship to a capable fault according to characteristics (1) or (2) above such that movement on one could be reasonably expected to be accompanied by movement on the other.*

The faults from the Quaternary fault and fold database within 300 kilometers of the Facility are shown on Figure 4-1. Capable faults must also meet the minimum criteria for fault length and distance from the Facility, as defined by NRC 10 CFR Appendix A to Part 100, and included in Table 4-1 in this report. A fault that is deemed capable by the criteria listed above, but does not meet the minimum criteria provided in Table 4-1, does not need to be considered in the seismic hazard analysis. For the detailed analysis, the faults within 100 kilometers of the Facility that met these criteria are shown on Figure 4-2. A tabulated list of the faults is included in Appendix B.1.

All faults meeting the requirements outlined in Table 4-1 were considered in this seismic study. This is a conservative approach because although the NRC defines a "capable fault" as one having *"movement at or near the ground surface at least once within the past 35,000 years or movement of a recurring nature within the past 500,000 years,"* including all identifiable faults with Quaternary displacement would include fault movement over the past 1.6 million years. This was done because sufficient information does not exist for many of the faults with

Quaternary displacement as to the timing of the last movement of the fault.

The USGS separates the faults with Quaternary displacement into classes. These classes are provided below, as described by USGS.

- For a Class A fault, geologic evidence demonstrates the existence of a Quaternary fault of tectonic origin, whether the fault is exposed by mapping or inferred from liquefaction or other deformational features.
- For a Class B fault, geologic evidence demonstrates the existence of Quaternary deformation, but either 1) the fault might not extend deeply enough to be a potential source of significant earthquakes, or 2) the currently available geologic evidence is too strong to confidently assign the feature to Class C but not strong enough to assign it to Class A.
- For a Class C fault, geologic evidence is insufficient to demonstrate 1) the existence of tectonic faulting, or 2) Quaternary slip or deformation associated with the feature.
- For a Class D fault, geologic evidence demonstrates that the feature is not a tectonic fault or feature; this category includes features such as joints, landslides, erosional or fluvial scarps, or other landforms resembling fault scarps but of demonstrable non-tectonic origin.

The faults with Quaternary displacement included in this analysis are either Class A or B. Descriptions from the USGS of the faults included in this analysis, are included in Appendix B.2.

### 4.1.2 Background Event

Earthquakes sometimes occur that are not associated with a known geologic structure. These events are termed "background events" or "floating earthquakes." Evaluation of background events allows for potential low to moderate earthquakes unassociated with tectonic structures to be considered in the seismic hazard of the Facility. The maximum magnitude for these background events within the Intermountain United States ranges between local magnitude ($M_L$) 6.0 and 6.5 (Woodward-Clyde, 1996). Larger earthquakes would be expected to leave a detectable surface expression, especially in arid to semiarid climates, with slow erosion rates and limited vegetation. In seismically less active areas such as the Colorado Plateau, the maximum magnitude associated with a background event is assumed to be 6.3, consistent with that used in seismic evaluations performed for uranium tailing sites in Green River (DOE 1991a, pg. 26), and Grand Junction (DOE 1991b, pg. 71).

#### *4.1.2.1 Background Event in Deterministic Analyses*

Background or floating earthquakes are typically evaluated deterministically by placing the largest earthquake that can be assumed to occur unassociated with a known fault, at a distance of 15 kilometers from the project location.

#### *4.1.2.2 Background Event in Probabilistic Analyses*

For probabilistic analyses, the hazard from background earthquakes is typically assessed using two approaches. The first approach uses areal source zones and assumes a uniformly distributed seismicity within the zone. The second approach uses gridded seismicity which

retains a degree of stationarity using 0.1-degree latitude and longitude grid spacing, as used by USGS for the NSHMP. Due to the fact that the historic seismic record within 100 km of the Facility contains a small number of earthquakes, determination of recurrence intervals for a site-specific areal source zone was not completed. EA used the 2014 gridded source zone for the CEUS and the 2014 shallow extensional gridded source zone for the WUS in our analyses.

## 4.2 Attenuation Relations

Attenuation of ground motions from the location of a seismic event to the site was calculated using attenuation relations. Due to the absence of abundant strong ground motion records, no specific attenuation relation exists solely for New Mexico. Therefore, we have used ground motion models (GMMs) appropriate for tectonically active crustal regions. The crustal GMMs that were used were developed as part of the NGA-West2 Project sponsored by the Pacific Earthquake Engineering Research (PEER) Center Lifelines Program. These models are also used by the USGS in developing the U.S. National Seismic Hazard Maps. EA used four of the five NGA-West2 GMMs in the analyses: Chiou and Youngs (2014), Campbell and Bozorgnia (2014), Abrahamson and others (2014), and Boore and others (2014). Idriss (2014) was not included due to its lack of a hanging wall model.

Three parameters (depth to $V_s$ of 1000 m/s and 2,500 m/s and average $V_s30$) need to be specified in order to use the above attenuation equations. The three parameters are related to the shear wave velocity of the underlying soil and rock.

### 4.2.1 Depth to Shear Wave Velocity of 1,000 m/s

The National Earthquake Hazards Reduction Program (NEHRP, 2003) issued a publication which discusses site classification for seismic design. The publication listed the site classes and corresponding shear wave velocities. This information is summarized in Table 4-2.

The first parameter is the depth at which the shear wave velocity ($V_s$) of the soil reaches 1,000 meters per second (m/s) which is in the rock category as shown in Table 4-2. Based on previous subsurface investigation that EA has completed at the site along with the published site geology, this parameter was assumed to be 5 meters.

### 4.2.2 Depth to Shear Wave Velocity of 2,500 m/s

The next parameter is the depth at which shear wave velocity of the profile reaches 2,500 m/s (hard rock according to Table 4-2). EA was provided with a site geophysical scan for a draft pilot hole issued by Dames and Moore. The geophysical scan included a compressive wave velocity ($V_p$) profile. EA used the $V_p$ profile in determining the depth to 2,500 m/s for the shear wave velocity. The $V_p$ values needed to be converted to $V_s$ values. EA used a common equation to convert the $V_p$ values to $V_s$ values.

$$Vs = Vp\sqrt{\frac{1-2\nu}{2(1-\nu)}}$$

where:

$V_s$ = shear wave velocity
$V_p$ = compression wave velocity
$\nu$ = Poisson's ratio

The geophysical scan also included information on Poisson's ratio. Using that information and empirical correlations published in Bowles (1982) that indicate Poisson's ratios ranging from 0.1 to 0.4 for rock, EA used a Poisson's ratio of 0.27 for the calculations, which is generally consistent with the surficial and bedrock materials. The profile indicates the approximate average depth to a shear wave velocity of 2,500 m/s is 0.79 kilometers below the ground surface.

### 4.2.3 Average Shear Wave Velocity for Upper 30 Meters

The next parameter to be specified is the average shear wave velocity of the upper 30 meters ($V_s30$) of the original ground surface. EA estimated an average $V_p30$ velocity for the profile and converted that to $V_s30$ using the above equation. The resulting $V_s30$ for the profiles 30 meters below the Facility was calculated to be 1,200 m/s. This value is in the rock category according to Table 4-2.

## 4.3 Deterministic Analysis

A deterministic analysis was completed for the Facility in order to determine which faults from the USGS Quaternary fault and fold database have the potential to produce PGAs of 0.05g or greater and would need further evaluation in a probabilistic model. A PGA of 0.05g is commonly used as a threshold value to streamline probabilistic hazard analysis by excluding sources unlikely to cause significant seismic shaking. PGA values around 0.05g are often seen as the threshold below which the ground shaking is considered negligible for most engineering purposes. In deterministic analyses, the ground motions from the maximum credible earthquake (MCE) associated with capable faults are attenuated to the site.

The seismic sources considered for the deterministic analysis include the previously described faults listed in Appendix B.1. The MCE associated with each fault was calculated based on correlations between fault surface rupture length and earthquake magnitude as presented by Wells and Coppersmith (1994). The ground motions from the MCE associated with the faults were attenuated to the Facility using the attenuation relations described in Section 4.2. Typically, ground motions of median plus one standard deviation are reported in deterministic analyses. The PGA was calculated using EZ-FRISK Version: 8.11 (Risk Engineering, 2024). Input and the complete deterministic spectra from the EZ-FRISK analysis are included in Appendix C.1 and C.2, respectively. The inputs and results of the deterministic analyses are also summarized in a table in the beginning of Appendix C.2.

## 4.4 Probabilistic Analysis

A probabilistic analysis was performed for the Facility in order to evaluate the amount of risk associated with larger PGAs calculated by the deterministic analysis. In probabilistic analyses, ground motions and the associated probability of exceedance are estimated for background seismicity and for earthquakes on specific faults in order to evaluate the amount of risk associated with the PGA.

For the purpose of the seismic hazard evaluation, a 10,000-year return period is adopted for evaluating long-term stability. For the probabilistic analysis, faults that are included in the USGS Quaternary fault and fold database and have the potential to produce PGAs of 0.05g or greater (based on deterministic methods) were selected for further evaluation in the probabilistic model. These criteria resulted in the inclusion of the following 9 faults:

1. Intrabasin faults on the Llano de Albuquerque (2121);
2. Jemez-San Ysidro fault (Jemez and San Ysidro sections) (2029ab);
3. Jemez-San Ysidro fault (Calabacillas section) (2029c);
4. Mesa Prieta faults (1985);
5. Nacimiento fault (northern and southern sections) (2002ab);
6. Sand Hill fault zone (2039);
7. Santa Fe fault (2123);
8. unnamed faults near Albuquerque Volcanoes (2049);
9. unnamed faults of El Malpais lava field (2146);

As discussed above, EA also included the 2014 CEUS gridded source and the 2014 shallow extensional WUS gridded source in our analyses. The gridded seismicity retains a degree of stationarity using 0.1-degree latitude and longitude grid spacing, as used by USGS for the NSHMP.

The USGS descriptions included in Appendix B.2 were used to determine fault characteristics where possible. Uncertainties in the fault characteristics are incorporated into the probabilistic analysis by representing the possible scenarios with a weight value. Maximum magnitudes for the faults were estimated based upon the empirical relationship developed by Wells and Coppersmith (1994) for surface rupture length, with an uncertainty of 0.3 corresponding to the standard error in the Wells and Coppersmith (1994) relationship. The recurrence relationships for the faults were modeled using maximum magnitude recurrence models. Slip rates are used to characterize rates of fault activity. However, very limited data was available regarding slip rates, and the USGS Fault and Fold Database categorizes all the considered faults as simply having a slip-rate less than 0.2 mm per year. Slip rates were therefore modeled as being 0.02 mm per year, similar to rates of activity assigned to many faults of questionable Quaternary activity in the Rio Grande Rift area east of the Colorado Plateau (Wong et. al., 2004).

The EZ Frisk probabilistic input is included in Appendix D.2. Table 4-3 shows the seismic source contribution to the total mean hazard at a return period of 10,000 years (1E-4 annual percent exceedance). The total hazard curve is shown in Figure 4-3 and the source contribution is shown in Figure 4-4. The complete results of the probabilistic analyses are included in Appendix D.3.

## 5.0 RESULTS AND CONCLUSIONS

EA conducted deterministic and probabilistic analyses for the 10,000-year return period seismic events to support stability analyses for the Facility.

The deterministic analysis showed that the random earthquake produced the highest PGA for the Facility. EA determined that the random earthquake with an MCE of magnitude of 6.3, located 15.1 km from the site, produced a mean PGA of 0.09g. Additionally, the Mesa Prieta faults are the closest faults to the site (~47 kilometers) and EA determined a maximum credible earthquake (MCE) of magnitude 6.3 for this fault based on the Wells and Coppersmith (1994) relationship. The deterministic PGA determined for the Busted Boiler Fault was 0.03g.

The probabilistic analyses show that the hazard is controlled by the gridded seismicity. For the probabilistic analysis, EA calculated a mean PGA of 0.21g for the 10,000-year return period. These values should be used in slope stability and other technical analyses as appropriate for the site.

To confirm the validity of these values, EA ran a cross check using a USGS screening-level methodology. The USGS maintains a *"USGS Earthquake Hazard Toolbox"* that has web applications for computing hazards for the USGS National Seismic Hazard Models. EA used the 2023 model (accessed in November 2025) as a screening tool for this site, which calculated PGA of 0.37g for the 10,000-year return period. It is likely that the majority of the difference between the USGS and the site-specific PGA is a result of using different attenuation relationships. The USGS applied some attenuation relations developed for the CEUS. However, using attenuation relations that are specific to normal extensional faulting is appropriate for this area.

## 6.0 LIMITATIONS

The opinions and recommendations in this report are based on a reasonable degree of certainty. This report has been prepared based upon review of the reference documents, geological analyses, and our experience. The conclusions presented represent our best judgment based on the information available. Should additional information become available we should be allowed to review that information and modify our conclusions accordingly.

# TABLES

**Table 4-1 Minimum Criteria for Faults Considered in Seismic Investigation (NRC 10 CFR Appendix A to Part 100)**

| **Distance from Facility (mi) (km)** | **Minimum length of fault to be considered (mi) (km)** |
|---|---|
| 0 – 20 (0-32) | 1 (1.6) |
| 20 – 50 (32.2-80.5) | 5 (8.0) |
| 50 – 100 (80.5-160.9) | 10 (16.1) |
| 100 – 150 (160.9-241.4) | 20 (32.2) |
| 150 – 200 (241.4-321.9) | 40 (64.4) |

Note: The numbers listed in parentheses are in kilometers.

**Table 4-2 National Earthquake Hazards Reduction Program (NEHRP) Site Class Definitions**

| **Soil Profile Type** | **Average Shear Wave Velocity to 30-meter Depth ($V_s$)** |
|---|---|
| A – Hard Rock | > 1500 m/s |
| B – Rock | $760 < v_s < 1500$ m/s |
| C – Very Dense Soil and Soft Rock | $360 < v_s < 760$ m/s |
| D – Stiff Soil Profile | $180 < v_s < 360$ m/s |
| E – Soft Soil Profile | < 180 m/s |

**Table 4-3 Hazard Contribution to Total Mean Hazard for 10,000-year Return Period, Probabilistic Analysis**

| Source Name | USGS Fault ID Number | Distance from Facility (km) | Peak Ground Acceleration (10,000-year return period) |
|---|---|---|---|
| USGS 2014 CEUS Gridded | --- | --- | 0.03 |
| USGS 2014 WUS Shallow Extensional Gridded | --- | --- | 0.21 |
| Total Hazard[1] | --- | --- | 0.21 |

Note: 1) The total hazard PGA is the PGA for a specific return period considering the sources all together. Refer to Figure 4-3 for a visual explanation of individual source PGAs and the total hazard for the Facility.

# USGS DESCRIPTION OF FAULTS MEETING THE NRC MINIMUM CRITERIA

U.S. Geological Survey - Earthquake Hazards Program

# Quaternary Fault and Fold Database of the United States

**As of January 12, 2017, the USGS maintains a limited number of metadata fields that characterize the Quaternary faults and folds of the United States. For the most up-to-date information, please refer to the interactive fault map.**

## Cat Mesa fault (Class A) No. 2122

**Last Review Date: 2016-04-11**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., and Jochems, A.P., compilers, 2016, Fault number 2122, Cat Mesa fault, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:16 AM.**

| | |
|---|---|
| **Synopsis** | The active trace of the Cat Mesa fault extends from south of New Mexico State Highway 6 (west of Los Lunas) northward along the eastern edge of Cat Mesa. At about its midpoint, the Cat Mesa fault splits into two north-trending splays that offset Upper Santa Fe Group sediment and die out near the western edge of the Llano de Albuquerque. The Cat Mesa fault(s) offsets and exposes the late Pliocene Cat Mesa basalt flow along the eastern edge of Cat Mesa. The Cat Mesa basalt flow is interbedded with the upper part of the upper Santa Fe Group, the Ceja Formation, 6–10 m below the Llano de Albuquerque, and is offset about 30 m near the middle of the fault. Early and middle Pleistocene surficial deposits are offset about 17 m (net) across the two fault strands near the northern end of the fault zone. The Cat Mesa fault lies to the west of the late Pleistocene basalts of the Cat Hills, but the Cat Mesa basalt flow may have originated from the volcanic fault and dike system that fed the younger Cat Hills basalt field. |
| **Name comments** | The Cat Mesa fault was originally mapped by Kelley (1954 #1222; 1977 #1106) and in more detail by Kelley and Kudo (1978 #1307). Minor modifications were made by Machette (1978 #1223; 1982 #1401), Machette and |

| | |
|---|---|
| | McGimsey (1983 #1024), Maldonado and Atencio (1998 #1778), and Maldonado (2003 #7453).<br><br>**Fault ID:** Fault no. 3 of Machette (1982 #1401), fault no. 2 of Machette and McGimsey (1983 #1024). |
| **County(s) and State(s)** | VALENCIA COUNTY, NEW MEXICO <br>BERNALILLO COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault traces from 1:24,000-scale geologic mapping in the Dalies NW and Rio Puerco 7.5-minute quadrangles (Maldonado and Atencio, 1998 #1778; Maldonado, 2003 #7453) combined with accurate placement of exposed traces using photogrammetric methods. <P> |
| **Geologic setting** | The Cat Mesa fault is an intrabasin fault near the western margin of the central Albuquerque-Belen basin. The Cat Mesa fault lies to the west of and does not offset the late Pleistocene basalts of the Cat Hills, but Kelley and Kudo (1978 #1307, fig. 20) inferred that the Cat Mesa basalt flow underlies and probably originated from the fault and dike system that fed the younger Cat Hills basalt field. Thus, the fault may be related to volcanic activity in the vicinity of the Cat Hills volcanic field. <P> |
| **Length (km)** | 20 km. |
| **Average strike** | N0°E |
| **Sense of movement** | Normal |
| **Dip Direction** | E; W<br><br>*Comments:* Maldonado and Atencio (1998 #1778) measured a dip of 80° toward the east-northeast where the Cat Mesa fault cuts sediment of the Ceja Formation. <P> |

| | |
|---|---|
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | The Cat Mesa fault is well expressed where the resistant Cat Mesa basalt flow is exposed in the fault zone. Elsewhere, the fault strands are marked by broad swales on the largely sand-covered Llano de Albuquerque. Machette and McGimsey (1983 #1024) estimated that the Cat Mesa basalt flow is offset about 30 m near the middle of the fault. They also estimated a total of 17 m of offset in early and middle Pleistocene deposits across the two fault strands near the northern end of the fault zone. <P> |
| **Age of faulted surficial deposits** | The Cat Mesa fault offsets the Cat Mesa basalt flow, dated at 3.0±0.1 Ma by <sup>40</sup>Ar/<sup>39</sup>Ar (Maldonado and Atencio, 1998 #1778). The Cat Mesa basalt flow is interbedded with the upper part of the upper Santa Fe Group, the Pliocene-early Pleistocene Ceja Formation (Machette, 1978 #1223; Maldonado and Atencio, 1998 #1778; Maldonado, 2003 #7453), 6–10 m below the Llano de Albuquerque (Kelley and Kudo, 1978 #1307). The two fault strands near the northern end of the fault zone offset the early Pleistocene (?) Llano de Albuquerque (Machette and McGimsey, 1983 #1024). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | middle and late Quaternary (<750 ka)<br><br>*Comments:* Machette and McGimsey (1983 #1024) documented offset of the early Pleistocene (?) Llano de Albuquerque. They also speculated that if the Cat Mesa fault is related to structures controlling the basalts of the Cat Hills volcanic field, then there may be late Pleistocene movement on the Cat Mesa fault. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* No detailed studies of fault offset or timing are available; low slip-rate category assigned based on evidence that the 3 Ma Cat Mesa basalt is offset about 30 m (Machette and McGimsey, 1983 #1024; Personius and others, 1999 #6930). |

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Machette, M.N., and Jochems, A.P., compilers, 2016, Fault number 2140, Cebollita Mesa fault, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:18 AM.**

| | |
|---|---|
| **Synopsis** | The Cebollita Mesa fault has seemingly young (<15 ka) movement, which is anomalous in the sense that there are few mapped Quaternary faults in this region, and in the Colorado Plateaus Province in general. However, field studies have shown that the fault has been recurrently active in the late Quaternary. Single-event scarps on the fault are about 2–2.5 m high, whereas older, late (?) Pleistocene, alluvium has compound (multiple-event) scarps as much as 8 m high. No dating has been conducted to refine the timing of last movement, slip rate, or recurrence interval for this down-to-the-west normal fault. |
| **Name comments** | This Quaternary fault was named by Levish and others (1992 #1715) for Cebollita Mesa, a Pliocene basalt-covered mesa located about 8 km east and northeast of the fault. The fault was first shown by Machette (1978 #1223) on the geologic map of the Socorro 1° x 2° quadrangle, but was overlooked by Machette and McGimsey (1983 #1024) in their later fault compilation. Maxwell (1986 #1720) made the first detailed geologic map that showed the fault, whereas Levish (1992 #1715) characterized its late Quaternary history as part of a dam hazards study. The fault is mapped for about 13 km across the toe slope of dissected Cretaceous bedrock hills. It extends from the north side |

| | |
|---|---|
| | of Bonine Canyon on the south, north past Head Windmill and New Mexico State Highway 117. About 1 km north of the highway, the fault disappears beneath a young basalt flow. |
| **County(s) and State(s)** | CIBOLA COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Trace from approximately 1:100,000-scale geologic map of Levish and others (1992 #1715) and 1:62,500-scale geologic map of Maxwell (1986 #1720) combined with accurate placement using photogrammetric methods. <P> |
| **Geologic setting** | The fault offsets the toe slope of dissected Cretaceous bedrock hills west of Cebollita Mesa. To the north, the fault disappears beneath a late Holocene basalt flow, but may continue further as suggested by as much as 300 m of down-to-the-west displacement on two normal faults imaged by shallow seismic-reflection profiling (Kelly and Reynolds, 1989 #1738). The Cebollita Mesa fault is subparallel to (but west of) similarly oriented normal faults that Maxwell (1986 #1720) maps as cutting Pliocene basalts of Cebollita Mesa. <P> |
| **Length (km)** | 13 km. |
| **Average strike** | N4°E |
| **Sense of movement** | Normal<br><br>*Comments:* As mapped by Maxwell (1986 #1720) and seen in natural exposures by Levish and others (1992 #1715). <P> |
| **Dip Direction** | W |

| | |
|---|---|
| | *Comments:* Although not mentioned by Levish and others (1992 #1715), the faults exposed in natural exposure have high-angle (near vertical) dips near the surface (Dan Levish, oral commun., 1988). <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | The fault forms a north-trending, left-stepping series of three en echelon scarps. Levish and others (1992 #1715) measured four scarp profiles: one (P-1) on the northern strand and three (P-2 to P-4) on the southern half of the southern strand. These profiles document single-event scarps of about 2.2–2.5 m height (1.9–2.0 m surface offset) and compound (multiple-event) scarps of about 6.0–8.5 m height (5.2–7.5 m surface offset). All four of the profiled scarps have modest maximum scarp-slope angles of 10–16°, but they are formed on relatively fine-grained, easily eroded sediment. Analysis of this data by Levish and others (1992 #1715) suggested that the younger scarps are late Pleistocene or Holocene in age, whereas as the larger scarps have morphology indicative of late Pleistocene movement. The scarp data suggests that the morphometric data from the younger scarps (P-3 and P-4) are similar to the Drum Mountains scarps (early Holocene) and the Bonneville shoreline (~17.5–18 ka). Conversely, the compound scarps have nearly identical maximum scarp-slope angles as the single-event scarps, suggesting that the steepness of all the scarps is controlled by the younger (<15 ka) event. <P> |
| **Age of faulted surficial deposits** | Maxwell (1986 #1720) mapped the faults as offsetting fine-grained Quaternary alluvium derived from Cretaceous sedimentary rock to the east. The smaller scarps are formed on alluvium of the lowest fluvial terrace, whereas the compound scarps are on alluvium that forms the next highest fluvial terrace. These deposits are likely to be latest or late Pleistocene in age (<130 ka). Levish and others (1992 #1715) reported that the scarps are locally muted (buried) by eolian sand. No studies or detailed mapping have been conducted to refine the age of the Quaternary sediment that are offset by the fault. To the north of New Mexico State Highway 117, the fault disappears beneath the McCartys basalt flow, which is estimated to be of late Holocene age, 2.4–3.9 ka (Laughlin and others, 1994 #7439; Maxwell, 1986 # 1720; Dunbar and Phillips, 2004 #7424). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | latest Quaternary (<15 ka)<br><br>*Comments:* Timing of most recent surface faulting based on scarp-morphology data (Levish and others, 1992 |

| | |
|---|---|
| | #1715) that is consistent with the continuity of the scarps, and expression on the lowest of the fluvial terraces of local streams that cross the scarps. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* It appears that the slip rate probably falls in the less than 0.2 mm/yr category because the 1.9–2.0 m of offset from the most recent event was the result of strain accumulation over 15–120 k.y. |

## Continental Divide fault (Class B) No. 2145

**Last Review Date: 2016-04-22**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Machette, M.N., and Jochems, A.P., compilers, 2016, Fault number 2145, Continental Divide fault, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:19 AM.**

| | |
|---|---|
| **Synopsis** | Little is known about this northeast-trending suspect fault; it reportedly forms a low but prominent scarp on Quaternary basalts of the North Plains lava field. The trend of the feature is parallel to a string of eruptive basalt cones that occupy the center of the field, which suggests that movement on the fault may be controlled by volcanism and deeper-seated crustal structures. No detailed studies have been conducted to determine the timing of movement or amount of offset of the basalt. Some authors have suggested that the scarp may be the result of volcanic processes, but its association with a mapped bedrock fault supports an interpretation of a tectonic origin. |
| **Name comments** | This suspect fault extends along the Continental Divide from about 3 km south of New Mexico State Highway 36 to 5 km north of Peñasco Lakes. Although unnamed by Anderson (1986 #1281), who first mapped it, Levish and others (1992 #1715) named it for its near coincidence with the Continental Divide. |

| | |
|---|---|
| **County(s) and State(s)** | CIBOLA COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Trace from 1:100,000-scale geologic map of the Fence Lake quadrangle compiled by Anderson (1986 #1281) and 1:24,000-scale geologic map of the Techado 7.5' quadrangle (Arkell, 1984 #7422) combined with accurate placement using photogrammetric methods. <P> |
| **Geologic setting** | This northeast-trending feature appears to offset the southern part of the North Plains lava field and is parallel to eruptive basalt cones that occupy the center of the field. These cones mark the southwestern trace of the Jemez lineament, which is one of many northeast-trending crustal structures that control the location of young volcanism within and outside of the northern Rio Grande rift in New Mexico. The southern end of the feature is mapped as cutting the Miocene (?) Fence Lake Formation (Anderson, 1986 #1281). If this association is not a spatial coincidence, it would support a tectonic origin. <P> |
| **Length (km)** | 17 km. |
| **Average strike** | N20°E |
| **Sense of movement** | Normal<br><br>*Comments:* As reported by Anderson (1986 #1281). <P> |
| **Dip Direction** | SE<br><br>*Comments:* Although no dips are reported, the general direction is inferred from a southeast-facing escarpment. <P> |

| | |
|---|---|
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | Fault forms a scarp of 2–3 m height (Orin Anderson, written commun., 1997) on basalts of the North Plains lava field. Levish and others (1992 #1715) argued that the scalloped appearance of the escarpment suggests it is a volcanic flow margin and not a fault. <P> |
| **Age of faulted surficial deposits** | This feature appears to offset Quaternary basalts according to Anderson (1986 #1281). The Jaralosa Draw lobe (flow), which extends west from the North Plains lava field and has also been called the Fence Lake flow, has a K-Ar age of 1.38±0.29 Ma (Laughlin and West, 1976 #7420). Other basalt flows in the North Plains field have returned Ar-Ar ages of approximately 0.6-0.7 Ma (Laughlin and others, 1993 #7421), consistent with the seemingly young appearance of cinder cones such as at Chimney Hill. |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* Timing poorly controlled. Based on presence of scarp on early to perhaps middle Quaternary basalt. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Low slip rate estimated from presence of scarp of 2–3 m height (Orin Anderson, written commun., 1997) on early to perhaps middle Quaternary basalt. |

## County Dump fault (Class A) No. 2038

**Last Review Date: 2015-02-19**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Haller, K.M., Personius, S.F., Olig, S.S., and McCalpin, J.P., compilers, 2015, Fault number 2038, County Dump fault, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:19 AM.**

| | |
|---|---|
| **Synopsis** | The County Dump fault is a down-to-the-east, north-trending normal fault located in the northern part of the Albuquerque-Belen basin. The fault offsets deposits of the upper Santa Fe Group, well-developed calcic soils of the Llano de Albuquerque, and about 155-ka basalt of the Albuquerque Volcanoes volcanic field. Repeated surface-faulting in the past 1 m.y. is expressed as a subdued, 24-m-high, up to 800-m-wide fault scarp across the Llano de Albuquerque and was first recognized during early geologic work in the region. An exposure of the fault at the now abandoned Bernalillo County landfill (dump) has been described in two detailed studies addressing the history of surface rupture. The most recent study used thermoluminescence (TL) ages and detailed soils analyses to constrain the time of the most recent surface-faulting event on the County Dump fault at 24 ka. |
| **Name comments** | The County Dump fault was originally mapped and named by Lambert (1968 #1396) for a down-to-the-east normal fault exposed at the now abandoned Bernalillo County landfill site, located about 1.5 km north of Interstate 40. Kelley (1977 #1106) renamed this structure the Nine Mile fault and included a down-to-the west fault south of Interstate 40 that was originally mapped by Lambert (1968 #1396). Machette (1982 #1401) used the name |

| | |
|---|---|
| | "Bernalillo County Dump fault" for this structure, but most workers since Kelley (1977 #1106) have used either "County Dump fault" (Machette, 1978 #1402; Hawley and Haase, 1992 #1304) or "Nine Mile fault zone" (Hawley and Whitworth, 1996 #1303) when referring to this structure. Cather and others (1997 #1763) called the northern end of the County Dump fault the "Centipede fault" in the Sky Village SE quadrangle. Herein we use the name "County Dump fault" as originally named by Lambert (1968 #1396) for the entire fault zone, because the "Nine mile fault" as mapped by Kelley (1977 #1106) and Hawley and Whitworth (1996 #1303) contains faults with both down-to-the-east and down-to-the-west displacements.<br><br>**Fault ID:** Fault no. 2 of Machette (1982 #1401), fault no. 1 of Machette and McGimsey (1983 #1024). |
| **County(s) and State(s)** | SANDOVAL COUNTY, NEW MEXICO <br>BERNALILLO COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:100,000 scale.<br><br>*Comments:* The trace of the County Dump fault is from Lambert (1968 #1396), Machette (1978 #1402), Cather and others (1997 #1763), air photo mapping by S.F. Personius (unpublished data, 1997), and high-resolution aeromagnetic data (U.S. Geological Survey and SIAL Geosciences Inc., 1997 #1722; Grauch and Millegan, 1998 #1721). <P> |
| **Geologic setting** | The County Dump fault is one of several north-trending intrabasin faults in the northern part of the Albuquerque-Belen basin. The fault also forms the western margin of a broad graben that confines some basalt flows of the Albuquerque Volcanoes volcanic field. The spatial association of the fault with the volcanic field may suggest a possible relationship with magmatic activity. <P> |
| **Length (km)** | 35 km. |
| **Average strike** | N5°E |

| | |
|---|---|
| **Sense of movement** | Normal |
| **Dip** | 75°–85° E.<br><br>*Comments:* Dip measurements are from near-surface fault exposures at the abandoned Bernalillo County landfill site (Lambert, 1968 #1396; Machette, 1978 #1402; McCalpin, 1997 #1767). <P> |
| **Paleoseismology studies** | The fault is well exposed in the northwest corner of the now abandoned Bernallilo County landfill. Here, the exposed County Dump fault offsets sands and gravels assigned to the Upper Buff or Ceja members of the Santa Fe Formation (Bryan and McCann, 1937 #1288; Kelley, 1977 #1106), which are now included in the Sierra Ladrones Formation of the upper Santa Fe Group (Hawley and others, 1991 #1302). The upper part of these rocks may be early Pleistocene in age. The fault also cuts the Llano de Albuquerque, an extensive Pleistocene surface formed on the Santa Fe Group. <P> Site 2038-1. Results from an early study of the natural exposure suggest that buried soils on colluvial deposits as young as 20–120 ka were deposited in response to large offsets (Machette, 1978 #1402). <P> Site 2038-2. The exposure at Bernalillo County landfill was re-excavated to address why previous estimates of displacement were so large and whether artificial exposures of the section might better reveal small scarp-derived colluvial deposits resulting from smaller displacement events. Six backhoe trenches that exposed the hanging wall deposits to a depth of 19–21 m below the surface were excavated for this study (McCalpin, 1997 #1767; McCalpin and others, 2006 #693). Interpretation of the exposures suggest that perhaps as many as 14 earthquakes occurred on the County Dump fault since the abandonment of the Llano de Albuquerque at 1.8-0.8 Ma (Connell and others, 2013 #7235); the timing of surface ruptures were constrained by thermoluminescence (TL) ages and quantitative analysis of soil properties developed on colluvial deposits deposited adjacent to the County Dump fault. Based on a number of assumptions, the mean vertical displacement in the past 14 events at this location is 1.2±0.6 m; it is not known if mean displacement at this location is a representative average for the fault or not (McCalpin and others, 2006 #693). <P> |
| **Geomorphic expression** | The County Dump fault is discontinuously exposed in upper Santa Fe Group sediment along the eastern Llano de Albuquerque. A broad, sand-covered, 24-m-high fault scarp, which is 800 m wide with maximum scarp-slope angle of 3.5° (McCalpin and others, 2006 #6931), marks the trace of the fault where it crosses the Llano de Albuquerque north of the Bernalillo County landfill exposure. The scarp is asymmetrical; the upper (erosional) part between the fault and scarp crest comprises only 25 percent of total scarp width. This asymmetry is used to substantiate the |

| | |
|---|---|
| | interpretation that large amount of deposition has occurred on the hanging wall since active fluvial deposition on the Llano de Albuquerque ceased. Further north, the County Dump fault skirts the western margin of the Albuquerque Volcanoes volcanic field, and extends northward as a broad escarpment on upper Santa Fe Group sediment and eroded remnants of the Llano de Albuquerque. South of the Bernalillo County dump exposure, the fault is exposed in upper Santa Fe Group sediment before ending a few kilometers south of Interstate Highway 40. <P> |
| **Age of faulted surficial deposits** | At the surface, the County Dump fault is in sands and gravels assigned to the Upper Buff or Ceja members of the Santa Fe Formation (Bryan and McCann, 1937 #1288; Kelley, 1977 #1106), which are now included in the Sierra Ladrones Formation of the upper Santa Fe Group (Hawley and others, 1991 #1302). Fault scarps are on the Llano de Albuquerque (1.8 Ma based on 40Ar/39Ar dating, Connell and others, 2013 #7235), an extensive early Pleistocene surface formed at the top of the Santa Fe Group and basalts dated at about155 ka of the Albuquerque Volcanoes volcanic field (Geissman and others, 1990 #1297; Peate and others, 1996 #1411). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | late Quaternary (<130 ka)<br><br>*Comments:* McCalpin and others (2006 #6931) report evidence of a possible 24-ka earthquake that only produced warping of near-surface sand deposits. In addition, thermoluminescence (TL) ages suggest that the additional surface-rupturing earthquakes occurred at 39 ka and 59 ka. Therefore, two and possibly three earthquakes have occurred in the late Quaternary. Machette (1978 #1402) suggested a similar time of 20 ka for the latest significant earthquake on the County Dump fault based on regional rate of pedogenic calcium carbonate accumulation. <P> |
| **Recurrence interval** | 41 k.y. (<300 ka)<br><br>*Comments:* McCalpin and others (2006 #6931) used thermoluminescence (TL) ages and quantitative soils analysis to estimate the timing of 14 earthquakes. Six thermoluminescence (TL) samples ranging from 4 ka (at the surface) to greater than 293 ka (8.3 m below the surface) constrain the age of the uppermost colluvial wedges; the age of older soils (8.3–17.3 m below the surface) was estimated based on accumulation rate of pedogenic calcium carbonate of 0.26 g CaCO<sup>3</sup> per thousand years, based on data from the upper part of the section. Recurrence intervals range from 4 to 202 k.y. and average 40.8 k.y.; a better constrained average of 29.5±11 k.y. is |

| | |
|---|---|
| | indicated if the longest and shortest intervals are not considered. The three most recent faulting events can be reconstructed from relationships in the highest trench and yielded ages of about 24 ka (0.4 m vertical displacement), 40–45 ka (0.35 m vertical displacement), and 75–80 ka (< 3.5 m vertical displacement). The earlier investigation by Machette (1978 #1402) provided average recurrence intervals of 90–190 ka because fewer faulting events were identified. |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Low slip-rate category assigned based on vertical-displacement rates from trenching at site 2038-2 described in McCalpin and others (2006 #6931), who suggest the vertical-displacement rate has not been constant over the past 1.6 m.y. However, the long-term and short-term (from the past two earthquakes) vertical-displacement rates are similar. Vertical-displacement rate for the County Dump fault at the Bernalillo County landfill can be constrained by the 24 m of far-field surface offset and the estimated 1–1.6 Ma age of the Llano de Albuquerque, resulting in a possible range in vertical-displacement rate of 0.015–0.024 mm/yr (McCalpin and others, 2006 #6931). The vertical-displacement rate would be lower and better constrained if the age for the Llano based on Connell and others (2013 #7235) were considered. McCalpin and others (2006 #6931) present a similar short-term vertical rate of 0.018 mm/yr based on cumulative offset in the past two earthquakes of 0.75 m. |

## Coyote Springs fault (Class A) No. 2114

**Last Review Date: 2016-03-30**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., and Jochems, A.P., compilers, 2016, Fault number 2114, Coyote Springs fault, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:20 AM.**

| | |
|---|---|
| **Synopsis** | The Coyote Springs fault (and the Santa Fe [2123] and Loma Pelada [2113] faults to the north and south, respectively) form the active southwestern margin of the Rio Grande rift. Specifically, the Coyote Springs fault forms the southwestern margin of the Belen sub-basin of the Albuquerque basin. Offsets of 12–15 m in lower and middle Pleistocene deposits and 1–3 m in upper Pleistocene deposits indicate recurrent Quaternary movement along the Coyote Springs fault. At its southern end, clear evidence of Quaternary faulting dies out at Mariano Draw, and at its northern end, fault scarps die out about 5 km north of Arroyo Monte Largo. |
| **Name comments** | Originally named the Coyote fault by Kelley (1977 #1106), this fault was renamed the Coyote Springs fault by Machette (1982 #1401) and Machette and McGimsey (1983 #1024), after Coyote Spring, which is located near the southwest corner of the Comanche Ranch 7.5-minute quadrangle. The fault is still referred to as the Coyote fault in places (e.g., Grauch and Connell, 2013 #7268), but it should not be confused with the Coyote fault [2128] that forms the western boundary of the Manzanita Mountains on the southeast side of the Belen sub-basin (Personius and others, 1999 #6930). Thus, we retain the name Coyote Springs fault. The fault extends from the southern end of the |

| | |
|---|---|
| | Santa Fe fault [2123] to the northern end of the Loma Pelada fault [2113] along the northeastern margin of the Sierra Ladrones.<br><br>**Fault ID:** Fault no. 6 of Machette (1982 #1401), fault no. 5 of Machette and McGimsey (1983 #1024). |
| **County(s) and State(s)** | VALENCIA COUNTY, NEW MEXICO <br>SOCORRO COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:250,000 scale.<br><br>*Comments:* Fault traces from Machette and McGimsey (1983 #1024) at1:250,00 scale on topographic base map. <P> |
| **Geologic setting** | The Coyote Springs fault forms the active southwestern margin of the Belen sub-basin of the Albuquerque basin in the Rio Grande rift (Grauch and Connell, 2013 #7268), with the apparent deactivation of the Comanche fault to the west (Kelley, 1977 #1106). Seismic reflection and 3D geophysical studies support Kelley's assumption that a shallow shelf or bench (Monte Largo bench) underlies the piedmont area between the Coyote Springs and Comanche faults (Russell and Snelson, 1994 #1186; Grauch and Connell, 2013 #7268). <P> |
| **Length (km)** | 17 km. |
| **Average strike** | N21°W |
| **Sense of movement** | Normal |
| **Dip** | 15–17° E.<br><br>*Comments:* Near the surface the fault probably has a relatively high angle (60°) dip. However, Russell and Snelson (1994 #1186) reported a very shallow dip of 15–17° E for the fault at about 5 km depth based on seismic reflection data. There is some controversy about the listric (shallow curving) nature of faults in the Albuquerque basin. <P> |

| | |
|---|---|
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | Prominent, but discontinuous (eroded) fault scarps are present on surficial deposits along the central part of the Coyote Springs fault, whereas the youngest scarps are found at the southern end of the fault. Machette (1982) and Machette and McGimsey (1983 #1024) measured offsets of 12–15 m in lower and middle Pleistocene deposits, and 1–3 m in upper Pleistocene deposits. Morphometric studies of the small scarps suggested possible early Holocene or latest Pleistocene ruptures (Machette and McGimsey, 1983 #1024). <P> |
| **Age of faulted surficial deposits** | The Coyote Springs fault offsets alluvial-fan deposits of early and middle Pleistocene age as much as 12–15 m along its northern part, and middle and late Pleistocene age along its southern part (Machette and McGimsey, 1983 #1024; Read and others, 2007 #7473). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | latest Quaternary (<15 ka)<br><br>*Comments:* Fault scarp morphology studies by Machette and McGimsey (1983 #1024) indicate possible latest Pleistocene or early Holocene movement on the southern part of the Coyote Springs fault north of Mariano Draw. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Low slip-rate category assigned based on fault scarp data from Machette (1982 #1401) and Machette and McGimsey (1983 #1024) which indicates offsets of 1–3 m in late Pleistocene (10–150 ka) alluvium and as much as 12–15 m in middle to early Quaternary deposits. |

## Intrabasin faults on the Llano de Albuquerque (Class A) No. 2121

**Last Review Date: 2016-05-24**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Jochems, A.P., and Personius, S.F., compilers, 2016, Fault number 2121, Intrabasin faults on the Llano de Albuquerque, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:20 AM.**

| | |
|---|---|
| **Synopsis** | These faults are mostly expressed by short faults that offset the early Pleistocene Llano de Albuquerque geomorphic surface. They are collected together as a group for the express purpose of description. Most of these intrabasin faults are partly to nearly completely covered by eolian sand, but on air photographs these features are marked by linear scarps, aligned drainages, and in some cases aligned ephemeral ponds. Quaternary displacement is unknown for most of these faults, but a few have scarps up to 3–12 m high. Some of these faults may be related to volcanic activity, such as those associated with the Wind Mesa and Los Lunas volcanic centers. |
| **Name comments** | This group of north-trending normal faults forms a series of horsts and grabens on the Llano de Albuquerque, west of Albuquerque. A thick cover of eolian sand covers most of the Llano de Albuquerque, which has led to varying orientations and configurations of mapped faults in this area (Kelley, 1977 #1106; Kelley and Kudo, 1978 #1307; Machette, 1982 #1401; Machette and McGimsey, 1983 #1024; Hawley and Haase, 1992 #1304; Wong and others, 1995 #1155; Hawley and Whitworth, 1996 #1303; Shroba and others, 2003 #7459; Thompson and others, 2009 #7460). Named faults include several strands of the West Mesa and Cat Mesa [2122] fault zones (Wong and others, |

| | |
|---|---|
| | 1995 #1155; Hawley and Whitworth, 1996 #1303), the Atrisco fault (Hawley and Haase, 1992 #1304), and the Lost Horizon and Wind Mesa faults (Connell, 2008 #7454). We exclude all but the Cat Mesa fault [2122] as specific fault names until more detailed mapping and fault studies are conducted. |
| **County(s) and State(s)** | SANDOVAL COUNTY, NEW MEXICO <br>SOCORRO COUNTY, NEW MEXICO <br>BERNALILLO COUNTY, NEW MEXICO <br>VALENCIA COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault traces compiled from 1:24,000-scale mapping of Love and others (1998 #7457), Maldonado and Atencio (1998 #1777, 1998 #1778), Love (1999 #7456), Maldonado, 2003 (#7453), Rawling (2003 #7458), Shroba and others (2003 #7459), McCraw and others (2006 #7255), and Thompson and others (2009 #7460). Additional traces from unpublished 1:24,000-scale mapping of Isleta 7.5-minute quadrangle by Love and others and 1:50,000-scale mapping of Albuquerque metropolitan area by Connell (2008 #7454). All traces compiled digitally and accurately placed using photogrammetric methods. Original fault traces digitized from Machette and McGimsey (1983 #1024) with supplemental geophysical data from Grauch and Millegan (1998 #1721) and U.S. Geological Survey and SIAL Geosciences Inc. (1997 #1722). The area is covered by thick sequences of eolian sand, so most fault strands are subdued and others may be obscured. <P> |
| **Geologic setting** | This group of intrabasin faults forms a broad zone within the Albuquerque-Belen basin of the Rio Grande rift. <P> |
| **Length (km)** | 101 km. |
| **Average strike** | N3°E |
| **Sense of movement** | Normal |
| **Dip Direction** | E; W |

| | |
|---|---|
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | These faults are marked by subdued, discontinuously exposed, mostly sand covered scarps on the Llano de Albuquerque. East of El Rincon (an erosional embayment into the Llano), these structures form an anastomosing group of horsts and grabens that are marked by linear scarps, aligned drainages, and aligned ephemeral ponds (Shroba and others, 2003 #7459; Connell, 2008 #7454; Thompson and others, 2009 #7460). Some of the down-to-the-west faults have linear ponds along their bases, apparently caused by damming of the prevailing east-southeast-flowing drainages. Machette and McGimsey (1983 #1024) measured offsets of 3–12 m on some of these faults on the Llano de Albuquerque. Included in this dataset are buried faults delineated from high-resolution aeromagnetic data (U.S. Geological Survey and SIAL Geosciences Inc., 1997 #1722; Grauch and Millegan, 1998 #1721; Grauch, 1999 #7241). Most of these faults are buried only by a thin (less than 10 m) cover of eolian sediment and probably cut deposits and soils associated with Llano de Albuquerque (Shroba and others, 2003 #7459; Thompson and others, 2009 #7460). However, it is possible that some do not cut post-Pliocene strata. <P> |
| **Age of faulted surficial deposits** | These faults offset the early Pleistocene Llano de Albuquerque. This diachronous surface overlies deposits spanning the interval from approximately 1.8–0.8 Ma (Connell and others, 2000 #7455; Connell and others, 2013 #7235). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | middle and late Quaternary (<750 ka)<br><br>*Comments:* Some of these faults offset the early Pleistocene Llano de Albuquerque surface as much as 12 m (Machette and McGimsey, 1983 #1024); these data indicate a recurrent history of faulting that in some cases probably extended at least into the middle Pleistocene following abandonment of the Llano de Albuquerque surface. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr |

| | |
|---|---|
| | *Comments:* Low slip-rate category assigned based on offsets of 3–12 m of the early Pleistocene (~1.8-0.8 Ma) Llano de Albuquerque (Machette and McGimsey, 1983 #1024; Connell and others, 2013 #7235). |

## Jemez-San Ysidro fault, Calabacillas section (Class A) No. 2029c

**Last Review Date: 2015-02-20**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Koning, D.J., Haller, K.M., and Jochems, A.P., compilers, 2015, Fault number 2029c, Jemez-San Ysidro fault, Calabacillas section, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:21 AM.**

| | |
|---|---|
| **Synopsis** | **General:** The Jemez-San Ysidro fault is a steeply east-dipping normal fault that, in part, forms the active western margin of the Rio Grande rift south of the Valles caldera. The fault is divided into sections on the basis of a 45° change in fault strike at the latitude of Cañones and evidence for young (Holocene) rupture along its southern section. The northern, northeast-striking section of the fault (Jemez section) is aligned with northeast-striking faults within the collapsed center of the Valles caldera and the Embudo fault, and is coincident with the Jemez Lineament. The central fault (San Ysidro section) merges with the southern fault (Calabacillas section) about 7 km south of the town of San Ysidro.<br><br>**Sections:** This fault has 3 sections. The Jemez-San Ysidro fault consists of a northeast-striking fault (the Jemez fault of Goff and Kron, 1980 #1099), and north-striking faults along the northwestern margin of the Albuquerque basin (the Jemez and San Ysidro faults of Woodward, 1987 #1130). The boundary between the northern (Jemez) and central (San Ysidro) sections is placed at the 45° change in fault strike near Cañones. The boundary between the central and southern (Calabacillas) sections is near Arroyo Piedra Parada, 7 km south of San Ysidro. These sections |

| | |
|---|---|
| | are distinguished primarily on the basis of younger demonstrated displacement on the Calabacillas section, a prominent down-to-the-east normal fault that offsets the west side of the Llano de Albuquerque along the western margin of the Rio Grande rift. |
| **Name comments** | **General:** The Jemez-San Ysidro fault extends from the latitude of the Albuquerque Volcanoes north to the southern rim of the Valles caldera near Highway 4. As used herein, the Jemez-San Ysidro fault includes the northeast-striking faults referred to as the Jemez fault zone by Goff and Kron (1980 #1099) and Goff and others (1981 #1182), the north-striking Sierrita fault of Woodward and DuChene (1975 #1131), Aldrich (1986 #1084), and Woodward (1987 #1130); the north-striking San Ysidro fault of Woodward and Ruetschilling (1976 #1133), Hawley and Galusha (1978 #1103), and Woodward (1987 #1130); and the north-striking Calabacillas fault of Bryan and McCann (1937 #1288, fig. 4), Wright (1946 #1427) and Cather and others (1997 #1763). All of these faults are grouped together herein because of lateral continuity (Wong and others, 1995 #1155; Koning and others, 1998 #7375).<br><br>**Section:** Part of the Calabacillas fault was originally mapped by Bryan and McCann (1937 #1288, fig. 4), and later described in detail by Wright (1946 #1427) in the Volcano Ranch 7.5 minute quadrangle. The fault was mapped and named in the Sky Village SE (now Arroyo de las Calabacillas) quadrangle by Cather and others (1997 #1763). Wright (1946 #1427, p. 426-428), Kelley and others (1976 #1380), and Kelley (1977 #1106) included the Calabacillas fault with the Sand Hill fault zone [2039], which is located 1–2 km to the west. However, detailed mapping indicates that the Calabacillas fault does not intersect the Sand Hill fault zone [2039] at the surface, but rather trends northeastward to the north and southeastward to the south of the exposures described by Wright (1946 #1427). At its northern end, the Calabacillas fault appears to join with the San Ysidro section near Arroyo Piedra Parada (Woodward and Ruetschilling, 1976 #1133; Koning and others, 1998 #7375). Connell (2008 #7454) and Grauch and Connell (2013 #7268) use the name San Ysidro fault for the entire fault zone south of the Rio Jemez, including all of what herein is named the Calabacillas section. |
| **County(s) and State(s)** | BERNALILLO COUNTY, NEW MEXICO <br>SANDOVAL COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br>COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale. |

| | |
|---|---|
| | *Comments:* The location of the fault is compiled from 1:24,000-scale mapping of the Cerro Conejo (previously Sky Village NE) quadrangle (Koning and others, 1998 #7375), the Arroyo de las Calabacillas (previously Sky Village SE) quadrangle (Cather and others, 1997 #1763), and the Volcanoes (previously Volcano Ranch) quadrangle (Thompson and others, 2009 #7460). The fault location is also evident in high-resolution aeromagnetic data (U.S. Geological Survey and SIAL Geosciences Inc., 1997 #1722; Grauch and Millegan, 1998 #1721) <P> |
| **Geologic setting** | The Jemez-San Ysidro fault forms the northwestern margin of the Albuquerque basin, although the amount of Quaternary vertical separation is less than that along other rift-margin faults. Aldrich (1986 #1084) stated that the fault was the western margin of the Rio Grande rift during the Oligocene, and that activity later stepped eastward to the Pajarito fault zone [2008]. Wong and others (1995 #1155) and House and Hartse (1995 #1160) identified seismicity aligned along the northern part of the fault. <P> |
| **Length (km)** | This section is 34 km of a total fault length of 92 km. |
| **Average strike** | N2°W (for section) versus N14°E (for whole fault) |
| **Sense of movement** | Normal |
| **Dip** | 60° E to near vertical<br><br>*Comments:* Dip measurement from Wright (1946 #1427, plate 8). McCalpin and others (2011 #7183) depict an exposure of the near-vertical main fault in a trench near the southern end of the fault. <P> |
| **Paleoseismology studies** | Site 2029-1. Two trenches were excavated 3 km north of the southern end of the fault (McCalpin and others, 2011 #7183). In the eastern trench, across a 5.3-m-high antithetic scarp, details of faulting are overprinted by stage IV soil carbonate that engulfs 4.5 m of exposed section, which bottoms in the Pliocene–Pleistocene (?) Santa Fe Group. McCalpin and others (2011 #7183) could distinguish five major depositional units, but the section was not sampled for dating. The western 60-m-long trench crosses a 27-m-high down-to-the-east fault scarp. The trench exposes Santa Fe Group only in the bottom of the exposed footwall. The interpretation of four prehistorical surface-faulting earthquakes is derived from observed vertical displacement of correlated buried soils and the six infrared-stimulated luminescence (IRSL) dates that are in correct stratigraphic order, substantiated by two fine-silt thermoluminescence (TL) ages, ranging from 14 ka to 219 ka. The IRSL dates were used to constrain the mean rate |

| | |
|---|---|
| | of secondary-carbonate accumulation in the soils to estimate the timing of the four surface ruptures interpreted at the site. <P> |
| **Geomorphic expression** | The Calabacillas fault forms broad, dissected fault scarps across the Llano de Albuquerque and is exposed in upper Santa Fe Group sediments at several locations where it crosses the Ceja del Rio Puerco. The northeast-trending part of the fault zone was mapped by Kelley and others (1976 #1380), Kelley (1977 #1106), Cather and others (1997 #1763), and Koning and others (1998 #7375); this northeast-striking part is marked by scattered displaced pediment remnants across the dissected surface of the Llano de Albuquerque. Wright (1946 #1427) reports 45-m-high scarps on the Llano; McCalpin and others (2011 #7183) describe the broad fault scarps as being 10–30 m high and having surface angles typically less than 5 degrees. <P> |
| **Age of faulted surficial deposits** | Kelley (1977 #1106) described minor offsets of pediment remnants on the northeast-trending section of the fault north of the Ceja del Rio Puerco exposures. The ages of these offset deposits are unknown, but they concluded that most are probably early and middle (?) Pleistocene in age. McCalpin and others (2011 #7183) reported displacement of buried soils dated to the middle and late Pleistocene. |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | latest Quaternary (<15 ka)<br><br>*Comments:* Based on trenching near the southern end of the fault, the most recent surface rupture occurred 14 k.y. ago (McCalpin and others, 2011 #7183). This age is assigned to the entire length of the fault, which is supported by the nine post-Llano de Albuquerque fault-scarp-derived colluvial and soil deposits adjacent to this structure described by Machette (1978 #1402) and Machette and others (1997 #1403). <P> |
| **Recurrence interval** | 9–20 k.y. (<55ka)<br><br>*Comments:* Based on six infrared-stimulated luminescence (IRSL) dates and one soil calcium-carbonate date, the timing of the most recent four surface-faulting events on the southern part of the fault is 14 ka, 23 ka, 35 ka, and 55 ka (McCalpin and others, 2011 #7183). The last four surface-rupturing earthquakes are not evenly spaced in time and individual recurrence intervals are between 9 k.y. and 20 k.y. McCalpin and others (2011 #7183) suggest that activity on the rift-bounding faults alternates and the east-dipping faults have been more active from the middle |

| | |
|---|---|
| | Pleistocene to present than the west-dipping faults. Soils developed on the colluvial wedges in the Ceja del Rio Puerco exposures also have extensive carbonate development (Machette and others, 1997 #1403), which indicates that a substantial amount of time is recorded in these deposits. |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* McCalpin and others (2011 #7183) report a long-term vertical-displacement rate of 0.027–0.054 mm/yr based on the 27-m-high scarp on the Llano de Albuquerque surface, assumed to be 0.5–1 Ma. Later work by Connell and others (2013 #7235) indicated that the Llano de Albuquerque surface is 0.8-1.8 Ma, which would decrease these long-term vertical-displacement rates. McCalpin and others (2011 #7183) further report vertical-displacement rates derived from each of the four recent earthquakes, which range from 0.011 to 0.028 mm/yr; although they acknowledge that vertical displacement at this site is likely smaller than that to the north. Displacement on the nearby antithetic fault (5.3 m) is not reported or removed from the vertical displacement referenced above; therefore, the reported vertical-displacement rates include maximum displacement for each event at this site. At a different location, Wright (1946 #1427) described about 45 m of accumulated fault-derived colluvial deposits on the downthrown block. All of these data suggest the Calabacillas section deforms at a rate lower than 0.2 mm/yr. |

# Quaternary Fault and Fold Database of the United States

**As of January 12, 2017, the USGS maintains a limited number of metadata fields that characterize the Quaternary faults and folds of the United States. For the most up-to-date information, please refer to the interactive fault map.**

## Jemez-San Ysidro fault, Jemez section (Class A) No. 2029a

**Last Review Date: 2016-06-26**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Jochems, A.P., Kelson, K.I., and Personius, S.F., compilers, 2016, Fault number 2029a, Jemez-San Ysidro fault, Jemez section, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:21 AM.**

**Synopsis**

**General:** The Jemez-San Ysidro fault is a steeply east-dipping normal fault that, in part, forms the active western margin of the Rio Grande rift south of the Valles caldera. The fault is divided into sections on the basis of a 45° change in fault strike at the latitude of Cañones and evidence for young (Holocene) rupture along its southern section. The northern, northeast-striking section of the fault (Jemez section) is aligned with northeast-striking faults within the collapsed center of the Valles caldera and the Embudo fault, and is coincident with the Jemez Lineament. The central fault (San Ysidro section) merges with the southern fault (Calabacillas section) about 7 km south of the town of San Ysidro.

**Sections:** This fault has 3 sections. The Jemez-San Ysidro fault consists of a northeast-striking fault (the Jemez fault of Goff and Kron, 1980 #1099), and north-striking faults along the northwestern margin of the Albuquerque basin (the Jemez and San Ysidro faults of Woodward, 1987 #1130). The boundary between the northern (Jemez) and central (San Ysidro) sections is placed at the 45° change in fault strike near Cañones. The boundary between the central and southern (Calabacillas) sections is near Arroyo Piedra Parada, 7 km south of San Ysidro. These sections are distinguished primarily on the basis of younger demonstrated displacement on the Calabacillas section, a

| | |
|---|---|
| | prominent down-to-the-east normal fault that offsets the west side of the Llano de Albuquerque along the western margin of the Rio Grande rift. |
| **Name comments** | **General:** The Jemez-San Ysidro fault extends from the latitude of the Albuquerque Volcanoes north to the southern rim of the Valles caldera near Highway 4. As used herein, the Jemez-San Ysidro fault includes the northeast-striking faults referred to as the Jemez fault zone by Goff and Kron (1980 #1099) and Goff and others (1981 #1182), the north-striking Sierrita fault of Woodward and DuChene (1975 #1131), Aldrich (1986 #1084), and Woodward (1987 #1130); the north-striking San Ysidro fault of Woodward and Ruetschilling (1976 #1133), Hawley and Galusha (1978 #1103), and Woodward (1987 #1130); and the north-striking Calabacillas fault of Bryan and McCann (1937 #1288, fig. 4), Wright (1946 #1427) and Cather and others (1997 #1763). All of these faults are grouped together herein because of lateral continuity (Wong and others, 1995 #1155; Koning and others, 1998 #7375).<br><br>**Section:** This part of the Jemez-San Ysidro fault was named the Jemez section by Wong and others (1995 #1155). The section extends from Highway 4 near Jemez Falls in the Jemez Mountains, southwest to Crow Springs, about 5 km west of Cañones. Smith (2004 #7529) connected this fault with the Cañones fault [2003]. |
| **County(s) and State(s)** | SANDOVAL COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | SOUTHERN ROCKY MOUNTAINS <br>COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Detailed geologic maps are available at a scale of 1:24,000 along the entire Jemez fault (Woodward and others, 1977 #1132), which was originally compiled and synthesized by Woodward (1987 #1130). More recent 1:24,000-scale maps include those of Osburn and others (2002 #7528) and Kelley and others (2003 #7527). Maps of selected parts of the fault are given by Goff and Kron (1980 #1099) at a scale of 1:12,000, and by Goff and Shevenell (1987 #1476) at a scale of 1:66,667. <P> |
| **Geologic setting** | The Jemez-San Ysidro fault forms the northwestern margin of the Albuquerque basin, although the amount of Quaternary vertical separation is less than that along other rift-margin faults. Aldrich (1986 #1084) stated that the fault was the western margin of the Rio Grande rift during the Oligocene, and that activity later stepped eastward to |

| | |
|---|---|
| | the Pajarito fault zone [2008]. Wong and others (1995 #1155) and House and Hartse (1995 #1160) identified seismicity aligned along the northern part of the fault. <P> |
| **Length (km)** | This section is 28 km of a total fault length of 92 km. |
| **Average strike** | N41°E (for section) versus N14°E (for whole fault) |
| **Sense of movement** | Normal |
| **Dip Direction** | V<br><br>*Comments:* The Jemez fault appears to be near vertical at the surface and in the shallow subsurface based on the relatively straight traces across rugged topography. Microseismicity in the vicinity of the Jemez fault appears to be aligned along a near-vertical zone, with a slight westerly dip (L. House, unpublished data, 1993). However, as a rift-margin fault, the Jemez fault probably dips to the east (Woodward and Ruetschilling, 1976 #1133). Wong and others (1995 #1155) considered dip values of 80° W, 90°, and 80° E, without a preferred dip to constrain the fault's geometry for seismic source characterization. <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | The Jemez section is marked by a prominent southeast-facing scarp across Virgin Mesa, which is underlain by the 1.2–1.3 Ma Tshirege Member of the Bandelier Tuff. Goff and Shevenell (1987 #1476) note a 15-m-high fault scarp on older travertine deposits near Soda Dam. <P> |
| **Age of faulted surficial deposits** | The youngest faulted bedrock is the 1.2–1.3 Ma Tshirege Member of the Bandelier Tuff. Tafoya (2012 #7530) obtained U-series ages of 210 ka and younger for calcite growth in the Jemez fault. These ages could relate to fault reactivation or infilling of younger sediment. |
| **Historic earthquake** | |
| **Most recent prehistoric** | undifferentiated Quaternary (<1.6 Ma) |

| | |
|---|---|
| **deformation** | *Comments:* The timing of the most-recent event is unknown. Prominent geomorphic expression across Virgin Mesa, displaced upper Bandelier Tuff suggest Quaternary deformation (Wong and others, 1995 #1155). Tafoya's (2012 #7530) U-series ages (<210 ka) on calcite growth in the Jemez fault allow for the possibility of middle or late Quaternary activity. Alternatively, the calcite growth may reflect younger geomorphic phenomena associated with fluvial deposition and incision. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Assigned slip rate category based on 12 m of separation of 1.2–1.3 Ma Tshirege Member of the Bandelier Tuff along the Jemez fault (Woodward, 1987 #1130) and 50 m of separation of the same unit along the fault reported by Goff and Shevenell (1987 #1476) and Goff and others (1989 #1098). |

# Quaternary Fault and Fold Database of the United States

**As of January 12, 2017, the USGS maintains a limited number of metadata fields that characterize the Quaternary faults and folds of the United States. For the most up-to-date information, please refer to the interactive fault map.**

## Jemez-San Ysidro fault, San Ysidro section (Class A) No. 2029b

**Last Review Date: 2015-02-20**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Kelson, K.I., Personius, S.F., Haller, K.M., Koning, D.J., and Jochems, A.P., compilers, 2015, Fault number 2029b, Jemez-San Ysidro fault, San Ysidro section, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:21 AM.**

**Synopsis**

**General:** The Jemez-San Ysidro fault is a steeply east-dipping normal fault that, in part, forms the active western margin of the Rio Grande rift south of the Valles caldera. The fault is divided into sections on the basis of a 45° change in fault strike at the latitude of Cañones and evidence for young (Holocene) rupture along its southern section. The northern, northeast-striking section of the fault (Jemez section) is aligned with northeast-striking faults within the collapsed center of the Valles caldera and the Embudo fault, and is coincident with the Jemez Lineament. The central fault (San Ysidro section) merges with the southern fault (Calabacillas section) about 7 km south of the town of San Ysidro.

**Sections:** This fault has 3 sections. The Jemez-San Ysidro fault consists of a northeast-striking fault (the Jemez fault of Goff and Kron, 1980 #1099), and north-striking faults along the northwestern margin of the Albuquerque basin (the Jemez and San Ysidro faults of Woodward, 1987 #1130). The boundary between the northern (Jemez) and central (San Ysidro) sections is placed at the 45° change in fault strike near Cañones. The boundary between the central and southern (Calabacillas) sections is near Arroyo Piedra Parada, 7 km south of San Ysidro. These sections

| | |
|---|---|
| | are distinguished primarily on the basis of younger demonstrated displacement on the Calabacillas section, a prominent down-to-the-east normal fault that offsets the west side of the Llano de Albuquerque along the western margin of the Rio Grande rift. |
| **Name comments** | **General:** The Jemez-San Ysidro fault extends from the latitude of the Albuquerque Volcanoes north to the southern rim of the Valles caldera near Highway 4. As used herein, the Jemez-San Ysidro fault includes the northeast-striking faults referred to as the Jemez fault zone by Goff and Kron (1980 #1099) and Goff and others (1981 #1182), the north-striking Sierrita fault of Woodward and DuChene (1975 #1131), Aldrich (1986 #1084), and Woodward (1987 #1130); the north-striking San Ysidro fault of Woodward and Ruetschilling (1976 #1133), Hawley and Galusha (1978 #1103), and Woodward (1987 #1130); and the north-striking Calabacillas fault of Bryan and McCann (1937 #1288, fig. 4), Wright (1946 #1427) and Cather and others (1997 #1763). All of these faults are grouped together herein because of lateral continuity (Wong and others, 1995 #1155; Koning and others, 1998 #7375).<br><br>**Section:** This part of the Jemez-San Ysidro fault was named the San Ysidro section by Wong and others (1995 #1155). The section extends from Crow Springs, about 5 km west of Cañones on the north to near Arroyo Piedra Parada, 7 km south of San Ysidro, where it joins with the Calabacillas section (e.g., Kelley, 1977 #1106; correlation implied by fault name convention of Koning and others, 1998 #7375; Connell, 2008 #7454). |
| **County(s) and State(s)** | SANDOVAL COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br>SOUTHERN ROCKY MOUNTAINS <br>COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Detailed geologic maps at a scale of 1:24,000 are available along the entire fault trace (Woodward and Ruetschilling, 1976 #1133; 1977 #1132), which are compiled and synthesized by Woodward (1987 #1130). Formento-Trigilio (1997 #1377) and Formento-Trigilio and others (1998 #7249) mapped Quaternary deposits and faults near Jemez Pueblo and San Ysidro at 1:24,000 scale. Additional detailed mapping of parts of the fault zone can be found in Koning and others (1998 #7375), Minor and Hudson (2006 #7246), and Caine and Minor (2009 #7244). <P> |

| | |
|---|---|
| **Geologic setting** | The Jemez-San Ysidro fault forms the northwestern margin of the Albuquerque basin, although the amount of Quaternary vertical separation is less than that along other rift-margin faults. Aldrich (1986 #1084) stated that the fault was the western margin of the Rio Grande rift during the Oligocene, and that activity later stepped eastward to the Pajarito fault zone [2008]. Wong and others (1995 #1155) and House and Hartse (1995 #1160) identified seismicity aligned along the northern part of the fault. <P> |
| **Length (km)** | This section is 34 km of a total fault length of 92 km. |
| **Average strike** | N2°W (for section) versus N14°E (for whole fault) |
| **Sense of movement** | Normal<br><br>*Comments:* Woodward and DuChene (1975 #1131) characterize movement along the fault as dominantly dip-slip with a minor right-slip component. Down-to-the-east normal displacement is consistent with the occurrence of Tertiary rift-fill sediments (Zia Sand Formation) on the east faulted against Precambrian rocks on the west (Woodward, 1987 #1130). <P> |
| **Dip** | 58°–70° E.<br><br>*Comments:* Hudson and others (2008 #7245) report the fault dips eastward at 58° to 70° based on magnetic susceptibility studies. Caine and Minor (2009 #7244) report variable oblique slip along strike based on slickenline data; the variation is controlled by the geometry of the fault, which is interpreted to have an average dip of 66° to the east (Caine and Minor, 2009 #7244). Advances in interpreting fault dip from aeromagnetic expression will improve the fault's three-dimensional geometry in the future. <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | Moderate geomorphic expression in bedrock is apparent on aerial photography, as a result of juxtaposition of different rock types and differential erosion. Short fault scarps and fault exposures in middle and late Pleistocene alluvial deposits have been mapped on several strands of the San Ysidro section near Jemez Pueblo and San Ysidro near the southern end of the fault (Formento-Trigilio and Pazzaglia, 1996 #1295; Formento-Trigilio, 1997 #1377; |

| | |
|---|---|
| | Formento-Trigilio and others, 1998 #7249). They measured offsets of 2–11 m on middle Pleistocene alluvial deposits along several strands of the fault. The numerous subparallel faults identified from high-resolution aeromagnetic data (Grauch and Hudson, 2007 #7243) are not included because of lack of reported recognized surface expression. <P> |
| **Age of faulted surficial deposits** | The youngest faulted bedrock mapped along the San Ysidro section is the Miocene Zia Sand Formation (Woodward and Ruetschilling, 1976 #1133; 1987 #1130). Formento-Trigilio and Pazzaglia (1996 #1295), Formento-Trigilio (1997 #1377), and Formento-Trigilio and others (1998 #7294) map and describe fault scarps on fluvial and alluvial-fan deposits in the Jemez River drainage. The clearest evidence of faulting is found in deposits that contain the Lava Creek B ash; these sediments were deposited about 620 ka (Izett and Wilcox, 1982 #1708; Sarna-Wojcicki and others, 1987 #1707). Formento-Trigilio and Pazzaglia (1996 #1295) and Formento-Trigilio (1997 #1377) also described probable offset of a 100–200 ka terrace strath; some offset deposits along the San Ysidro section may be late Pleistocene in age. |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | middle and late Quaternary (<750 ka)<br><br>*Comments:* The timing of the most-recent event is unknown. Formento-Trigilio and Pazzaglia (1996 #1295) and Formento-Trigilio (1997 #1377) found offsets in 620-ka alluvial deposits, and probable faulting of a middle- to late-Pleistocene (100–200 ka) fluvial terrace. These relations indicate that the San Ysidro section has been active in middle and probably late Pleistocene time. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Formento-Trigilio and Pazzaglia (1996 #1295) and Formento-Trigilio (1997 #1377) measured offsets of as much as 6–11 m on several strands of the San Ysidro section in alluvial deposits containing the 620 ka Lava Creek B ash; these data support a low long-term slip rate. |

## Nacimiento fault, northern section (Class A) No. 2002a

**Last Review Date: 2015-12-14**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Kelson, K.I., Jochems, A.P., and Personius, S.F., compilers, 2015, Fault number 2002a, Nacimiento fault, northern section, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:22 AM.**

**Synopsis**

**General:** The Nacimiento fault is an east-dipping fault bordering the Nacimiento uplift, an 80-km-long, 10- to 16-km-wide uplift related to Laramide deformation. The fault merges with the Gallina fault to the north, and dies out to the south into a broad anticline. The relatively high level of contemporary microseismicity within the Sierra Nacimiento may be related to deformation in the hanging wall of the fault. Detailed mapping along the southern part of the fault shows several short normal faults with both down-to-the-east and down-to-the-west displacements in Quaternary deposits. Down-to-the-east displacements may indicate normal reactivation of the Nacimiento reverse fault in the late Quaternary.

**Sections:** This fault has 2 sections. Woodward (1987 #1130) mapped the Nacimiento and Pajarito faults along the western margin of the Sierra Nacimiento. He noted the lack of continuity between these faults in the vicinity of San Miguel Canyon (section boundary), about 3 km southeast of the village of San Miguel. North of San Miguel Canyon, the fault generally has a lower dip and is a thrust fault, whereas south of San Miguel Canyon the fault is a high-angle reverse fault. Wong and others (1995 #1155) considered potential fault-rupture scenarios that included

| | |
|---|---|
| | rupture on either a northern section or a southern section, and on both sections together. These sections are considered separately here. |
| **Name comments** | **General:** The Nacimiento fault extends from Red Mesa, 7 km west of San Ysidro on the south, to the northern end of Sierra Nacimiento, 7 km northeast of Regina. The Nacimiento fault forms the western margin of the Laramide Nacimiento uplift. As used herein, the Nacimiento fault includes the Nacimiento and Pajarito faults of Woodward (1987 #1130), to avoid confusion with the Pajarito fault [2008] along the western margin of the Rio Grande rift near Los Alamos.<br><br>**Section:** This part of the Nacimiento fault was defined as the northern section by Wong and others (1995 #1155). The northern section extends from San Miguel Canyon about 3 km southeast of the village of San Miguel to the northern end of Sierra Nacimiento, 7 km northeast of Regina. |
| **County(s) and State(s)** | RIO ARRIBA COUNTY, NEW MEXICO <br>SANDOVAL COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Detailed geologic maps at a scale of 1:24,000 are available along the entire fault trace; 1:24,000 maps covering the northern section are those of Woodward and others (1972 #7292; 1973 #7293) and Merrick and Woodward (1982 #7291). These maps are compiled and synthesized by Woodward (1987 #1130). The location of the fault was digitized at 1:24,000 scale using photogrammetry to accurately map its trace from these maps. The fault was also mapped by Renick (1931 #1140) at a scale of 1:125,000 and by Wood and Northrop (1946 #1143) at a scale of about 1:95,000. <P> |
| **Geologic setting** | The Nacimiento fault is high-angle and over much of its geologic history a west-vergent reverse fault. The Nacimiento uplift is a north-south elongated structural block that lies west of the Jemez Mountains and forms the eastern margin of the San Juan Basin of the Colorado Plateau. Structural relief of the uplift formed during Laramide deformation, with shortening taking place via folding and reverse movement along the Nacimiento fault. The fault is west of the western margin of the Rio Grande rift. Quaternary normal faulting near Arroyo Peñasco |

| | |
|---|---|
| | documented by Formento-Trigilio and Pazzaglia (1996 #1295), Formento-Trigilio (1997 #1377), and Formento-Trigilio and Pazzaglia (1998 #2847) may indicate normal reactivation of the Nacimiento reverse fault. The relatively high level of contemporary microseismicity within the Sierra Nacimiento supports the interpretation of Quaternary deformation in the hanging wall of the fault (Wong and others, 1995 #1155; House and Hartse, 1995 #1160). <P> |
| **Length (km)** | This section is 36 km of a total fault length of 82 km. |
| **Average strike** | N3°E (for section) versus N1°W (for whole fault) |
| **Sense of movement** | Normal<br><br>*Comments:* West-vergent thrusting occurred during Laramide deformation. Sense of movement associated with contemporary microseismicity is unknown, but normal backslip may be likely in the present extensional regime. <P> |
| **Dip** | 45°–60° E.<br><br>*Comments:* Bedrock exposures of the fault noted by Woodward (1987 #1130) provide near-surface data on fault dip. Woodward (1987 #1130) speculates that the fault steepens with depth, although there are no published deep structural data for the fault. <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | Prominent west-facing range front of the Sierra Nacimiento is coincident with the Nacimiento fault. Baltz (1967 #1167) did not find geomorphic evidence of late Quaternary movement. Formento-Trigilio and Pazzaglia (1998 #2847) described low to moderate scarps on middle to late Pleistocene terrace and pediment-fan surfaces along the southern section <P> |
| **Age of faulted surficial deposits** | Youngest faulted bedrock is Cretaceous in age, although there are little or no data on the presence or absence of displaced late Quaternary deposits along the northern section. Manley and others (1987 #1119) map undisplaced Quaternary gravel across the fault trace at Rito de los Pinos, about 10 km northeast of the town of Cuba. |

| | |
|---|---|
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* Timing of most-recent event on northern section unknown. Prominent geomorphic expression along the range front and possible association with contemporary microseismicity suggest late Quaternary activity (Wong and others, 1995 #1155; House and Hartse, 1995 #1160). <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Low slip-rate category assigned based on the lack of evidence for Quaternary displacement along the northern section. |

## Nacimiento fault, southern section (Class A) No. 2002b

**Last Review Date: 2015-12-14**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Kelson, K.I., Jochems, A.P., and Personius, S.F., compilers, 2015, Fault number 2002b, Nacimiento fault, southern section, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:23 AM.**

**Synopsis**

**General:** The Nacimiento fault is an east-dipping fault bordering the Nacimiento uplift, an 80-km-long, 10- to 16-km-wide uplift related to Laramide deformation. The fault merges with the Gallina fault to the north, and dies out to the south into a broad anticline. The relatively high level of contemporary microseismicity within the Sierra Nacimiento may be related to deformation in the hanging wall of the fault. Detailed mapping along the southern part of the fault shows several short normal faults with both down-to-the-east and down-to-the-west displacements in Quaternary deposits. Down-to-the-east displacements may indicate normal reactivation of the Nacimiento reverse fault in the late Quaternary.

**Sections:** This fault has 2 sections. Woodward (1987 #1130) mapped the Nacimiento and Pajarito faults along the western margin of the Sierra Nacimiento. He noted the lack of continuity between these faults in the vicinity of San Miguel Canyon (section boundary), about 3 km southeast of the village of San Miguel. North of San Miguel Canyon, the fault generally has a lower dip and is a thrust fault, whereas south of San Miguel Canyon the fault is a high-angle reverse fault. Wong and others (1995 #1155) considered potential fault-rupture scenarios that included

| | |
|---|---|
| | rupture on either a northern section or a southern section, and on both sections together. These sections are considered separately here. |
| **Name comments** | **General:** The Nacimiento fault extends from Red Mesa, 7 km west of San Ysidro on the south, to the northern end of Sierra Nacimiento, 7 km northeast of Regina. The Nacimiento fault forms the western margin of the Laramide Nacimiento uplift. As used herein, the Nacimiento fault includes the Nacimiento and Pajarito faults of Woodward (1987 #1130), to avoid confusion with the Pajarito fault [2008] along the western margin of the Rio Grande rift near Los Alamos.<br><br>**Section:** This part of the Nacimiento fault was defined as the southern section by Wong and others (1995 #1155). The southern section extends from U.S. Highway 44 about 7 km west of the village of San Ysidro, northward to San Miguel Canyon about 3 km southeast of the village of San Miguel. |
| **County(s) and State(s)** | SANDOVAL COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Detailed geologic maps at a scale of 1:24,000 are available along the entire fault trace; 1:24,000 maps covering the southern section include those of Woodward and Schumacher (1973 #7295) and Woodward and others (1973 #7293; 1977 #1132). These maps are compiled and synthesized by Woodward (1987 #1130). In addition, detailed mapping of Quaternary deposits at 1:24,000 scale at the southern end of the fault has been completed by Formento-Trigilio and Pazzaglia (1996 #1295), Formento-Trigilio (1997 #1377), and Formento-Trigilio and others (1998 #7294). The location of the fault was digitized at 1:24,000 scale using photogrammetry to accurately map its trace from these maps. The fault also was mapped by Renick(1931 #1140) at a scale of 1:125,000, by Wood and Northrop (1946 #1143) at a scale of about 1:95,000, and by Baltz (1967 #1167) at a scale of 1:63,360. <P> |
| **Geologic setting** | The Nacimiento fault is high-angle and over much of its geologic history a west-vergent reverse fault. The Nacimiento uplift is a north-south elongated structural block that lies west of the Jemez Mountains and forms the |

| | |
|---|---|
| | eastern margin of the San Juan Basin of the Colorado Plateau. Structural relief of the uplift formed during Laramide deformation, with shortening taking place via folding and reverse movement along the Nacimiento fault. The fault is west of the western margin of the Rio Grande rift. Quaternary normal faulting near Arroyo Peñasco documented by Formento-Trigilio and Pazzaglia (1996 #1295), Formento-Trigilio (1997 #1377), and Formento-Trigilio and Pazzaglia (1998 #2847) may indicate normal reactivation of the Nacimiento reverse fault. The relatively high level of contemporary microseismicity within the Sierra Nacimiento supports the interpretation of Quaternary deformation in the hanging wall of the fault (Wong and others, 1995 #1155; House and Hartse, 1995 #1160). <P> |
| **Length (km)** | This section is 45 km of a total fault length of 82 km. |
| **Average strike** | N4°W (for section) versus N1°W (for whole fault) |
| **Sense of movement** | Normal<br><br>*Comments:* West-vergent reverse faulting occurred during Laramide deformation on the Nacimiento fault (Woodward, 1987 #1130). Sense of movement associated with contemporary microseismicity is unknown, but down-to-the-east and down-to-the-west Quaternary normal faults have been mapped by Formento-Trigilio and Pazzaglia (1996 #1295), Formento-Trigilio (1997 #1377), and Koning and others (1998 #7375) near Arroyo Peñasco and Cañada de las Milpas at the southern end of the fault. The down-to-the-west normal faults are in the footwall of the Nacimiento reverse fault, but the down-to-the-east Quaternary movement on one fault strand may be interpreted as normal backslip on a splay of the reverse fault (Formento-Trigilio and Pazzaglia, 1996 #1295; Formento-Trigilio, 1997 #1377). <P> |
| **Dip** | 75°–90° E.<br><br>*Comments:* Bedrock exposures of the fault noted by Woodward (1987 #1130) provide near-surface data on fault dip. Although exposures of the main trace of the Laramide Nacimiento fault clearly show steep east dips, west dipping synthetic and antithetic faults are locally present (Woodward, 1987 #1130). Formento-Trigilio and Pazzaglia (1996 #1295) and Formento-Trigilio (1997 #1377) mapped several normal faults in Quaternary deposits with both east and west dips near Arroyo Peñasco at the southern end of the Nacimiento fault. Woodward (1987 #1130) speculated that the fault steepens with depth, although no published subsurface structural data are available to confirm this interpretation. <P> |

| | |
|---|---|
| **Paleoseismology studies** | Formento-Trigilio and Pazzaglia (1996 #1295), Formento-Trigilio (1997 #1377), and Formento-Trigilio and others (1998 #7294) mapped Quaternary deposits and faults in detail near Arroyo Peñasco at the southern end of the Nacimiento fault. Most of the Quaternary faults mapped by these workers dip west, opposite to the dip of the bedrock fault mapped by Woodward (1987 #1130) in the area. These faults are as much as 2 km long and are marked by scarps up to 17 m high, although some of this apparent displacement may be related to landsliding in the underlying Triassic shale bedrock. Down-to-the-east Quaternary displacement of 4.2 m of travertine-cemented alluvium on one fault strand on the north rim of Arroyo Peñasco may either represent normal reactivation on a trace of the Nacimiento reverse fault mapped by Woodward (1987 #1130), or is an antithetic splay to the down-to-the-west faults mapped further east by Formento-Trigilio and Pazzaglia (1996 #1295) and Formento-Trigilio (1997 #1377). <P> |
| **Geomorphic expression** | The prominent west-facing range front of the Sierra Nacimiento is coincident with the Nacimiento fault. Baltz (1967 #1167) did not identify geomorphic evidence of late Quaternary activity, but Formento-Trigilio and Pazzaglia (1996 #1295) and Formento-Trigilio (1997 #1377) discuss evidence of multiple fault strands with Quaternary displacement along the southern end of the Sierra Nacimiento near Arroyo Peñasco. Scarps on middle to late Pleistocene terrace and pediment-fan surfaces in this area are up to 4.2 m high (Formento-Trigilio and Pazzaglia, 1998 #2847). <P> |
| **Age of faulted surficial deposits** | Although the youngest faulted bedrock mapped along the Nacimiento fault is Cretaceous in age (Woodward, 1987 #1130), Formento-Trigilio and Pazzaglia (1996 #1295) and Formento-Trigilio (1997 #1377) map fault scarps and infer displacements from geomorphic data in late Pleistocene alluvial deposits near Arroyo Peñasco at the southern end of the Nacimiento fault. Uranium-series ages on faulted, travertine-cemented alluvium indicate the faulted alluvium was deposited between about 270 ka and about 60 ka (Formento-Trigilio, 1997 #1377). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | middle and late Quaternary (<750 ka)<br><br>*Comments:* Timing of most-recent event is from uranium-series dating of faulted travertine-cemented alluvium by Formento-Trigilio (1997 #1377) that bracket the age of the offset alluvium between about 270 ka and 60 ka. <P> |

| | |
|---|---|
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Wong and others (1995 #1155) conservatively estimated a range in slip rate of 0.01 to 0.23 mm/yr for the Nacimiento fault, with a preferred value of 0.02 mm/yr, based on analysis of slip rates on analogous faults in the Rio Grande rift (Formento-Trigilio and Pazzaglia, 1996 #1295; Formento-Trigilio, 1997 #1377). A rate of up to 0.07 mm/yr may be permissible depending on the age of displaced travertine-cemented alluvium (Personius and others, 1999 #6930). |

## San Felipe fault zone, Algodones section (Class A) No. 2030b

**Last Review Date: 2016-06-28**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., Kelson, K.I., and Jochems, A.P., compilers, 2016, Fault number 2030b, San Felipe fault zone, Algodones section, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:29 AM.**

| | |
|---|---|
| **Synopsis** | **General:** The San Felipe fault zone is a broad zone of normal faults that offset basalts of the San Felipe volcanic field and underlying Santa Fe Group sedimentary rocks. The fault zone is best expressed where individual fault strands offset the volcanic tablelands of Santa Ana Mesa. The fault zone is primarily a graben, centered on the westernmost of two north-trending eruptive centers in the volcanic field. This structure, the San Felipe graben, is bound on the west by the down-to-the-east Luce and Santa Ana faults, and on the east by the down-to-the-west Algodones fault. Most of these faults offset the 2.4–2.6 Ma basalt flows of the San Felipe volcanic field. Average displacements on most faults are 15–30 m, although some of the larger structures, such as the Luce fault, have as much as 90–120 m of vertical displacement.<br><br>**Sections:** This fault has 2 sections. Wong and others (1995 #1155) used the polarity of faults in the San Felipe fault zone to delineate two sections: down-to-the-east faults that form the western margin of the San Felipe graben (Santa Ana and Luce faults) are included in the Santa Ana section, and down-to-the-west faults that form the eastern margin of the graben (Algodones fault) are include in the Algodones section. They assumed that one of |

| | |
|---|---|
| | these sections is a "master fault" that controls both sections, but they did not have enough subsurface data to support either scenario. |
| **Name comments** | **General:** This complex of numerous, generally north-trending normal faults near Santa Ana Mesa was first mapped in detail by Soister (1952 #1418). Kelley (1954 #1222) followed Soister's mapping closely in his compilation, and applied the name San Felipe fault zone to these structures. Later maps by Smith and others (1970 #1125), Kelley (1977 #1106), and Kelley and Kudo (1978 #1307) show similar fault patterns. Kelley (1977 #1106) named many of the more prominent structures in the zone, such as the Santa Ana, Luce, Cocida, and Algodones faults and the San Felipe graben. In their compilation, Wong and others (1995 #1155) used the name "San Felipe fault zone".<br><br>**Section:** The Algodones section includes the Algodones fault of Kelley (1977 #1106) and numerous smaller displacement down-to-the-west faults that form the east flank of the San Felipe graben. Some strands of the Algodones section of the San Felipe fault zone have been projected southward across the Rio Grande and connected with parts of the Valley View fault (Kelley, 1977 #1106; Wong and others, 1995 #1155), but detailed mapping by Connell (1995 #1291), Connell and others (1995 #1764), and Cather and Connell (1998 #7435) shows that strands of the Valley View fault trend northeasterly at their northern ends and probably do not connect with the San Felipe fault zone. |
| **County(s) and State(s)** | SANDOVAL COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault locations are good where faults cut volcanic rocks, but locations are poor in the less resistant Santa Fe Group rocks. Fault traces are from 1:24,000-scale maps of Cather and Connell (1998 #7435), Connell (1998 #7502), Smith and Kuhle (1998 #1771), Chamberlin and others (1999 #7524), and Personius (2002 #7526). A.P. Jochems used photogrammetric methods to accurately place fault traces in some locations. <P> |
| **Geologic setting** | The San Felipe fault zone is located in the western part of the Santo Domingo basin of the Rio Grande rift as defined by Smith and others (2001 #7438). The Santo Domingo basin links the en echelon Albuquerque and Española |

| | |
|---|---|
| | basins, and kinematic and paleostress evidence suggests that the basin functions as a relay that began to narrow in Plio-Pleistocene time (Minor and others, 2013 #7437). The fault zone forms a north-trending graben within the San Felipe volcanic field. Although Wong and others (1995 #1155) conclude that this graben is a minor sub-basin within the Rio Grande rift, the narrowing of the fault zone within the volcanic field indicates that the geometry of the fault zone may be in part controlled by volcanic activity (for example, van Wyk de Vries and Merle, 1996 #1422). <P> |
| **Length (km)** | This section is 45 km of a total fault length of 48 km. |
| **Average strike** | N7°W (for section) versus N1°E (for whole fault) |
| **Sense of movement** | Normal |
| **Dip** | 64–74° W<br><br>*Comments:* Dips of 64–74° are reported for west-dipping faults belonging to the Algodones section of the San Felipe fault zone (Connell, 1998 #7502; Personius, 2002 #7526). In addition, Connell (1998 #7502) reported a dip of 77° toward the east along one of the few east-dipping strands in the Algodones section 1.5 km northwest of Canjilon Hill in the Bernalillo 7.5-minute quadrangle <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | The Algodones fault and other faults that cut the basalt flows of the San Felipe volcanic field are well preserved as escarpments covered by basalt talus. Where these structures are located in Santa Fe Group rocks, fault expression is poor. Soister (1952 #1418) and Kelley (1977 #1106) measured average displacements of 15–30 m in basalts on most structures in the San Felipe fault zone, and as much as 90–120 m on larger structures such as the Luce fault in the Santa Ana section. <P> |
| **Age of faulted surficial deposits** | Faults in the Algodones section offset the 2.4-2.6 Ma (Bachman and Mehnert, 1978 #1265; Smith and Kuhle, 1998 #1771) basalts of the San Felipe volcanic field and underlying Santa Fe Group sedimentary rocks. Soister (1952 #1418) describes offset of his early Pleistocene Mesita Alta gravel and surface, which overlies San Felipe basalt flows in several places. |

| | |
|---|---|
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* No detailed studies of the age of most recent movement have been conducted. However, early Pleistocene gravels are offset locally and 90–120 m of post-San Felipe basalt (2.4-2.6 Ma) displacement has occurred. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Wong and others (1995 #1155) calculated long-term slip rates of 0.01–0.04 mm/yr based on 90–120 m of displacement that has occurred on the Luce fault since deposition of the San Felipe basalt (2.4-2.6 Ma) and similar data. They also concluded that it is likely that some of the major faults within the San Felipe fault zone act as independent rupture segments, but could not rule out the possibility that some faults rupture together. |

| | |
|---|---|
| **Synopsis** | **General:** The San Felipe fault zone is a broad zone of normal faults that offset basalts of the San Felipe volcanic field and underlying Santa Fe Group sedimentary rocks. The fault zone is best expressed where individual fault strands offset the volcanic tablelands of Santa Ana Mesa. The fault zone is primarily a graben, centered on the westernmost of two north-trending eruptive centers in the volcanic field. This structure, the San Felipe graben, is bound on the west by the down-to-the-east Luce and Santa Ana faults, and on the east by the down-to-the-west Algodones fault. Most of these faults offset the 2.4–2.6 Ma basalt flows of the San Felipe volcanic field. Average displacements on most faults are 15–30 m, although some of the larger structures, such as the Luce fault, have as much as 90–120 m of vertical displacement.<br><br>**Sections:** This fault has 2 sections. Wong and others (1995 #1155) used the polarity of faults in the San Felipe fault zone to delineate two sections: down-to-the-east faults that form the western margin of the San Felipe graben (Santa Ana and Luce faults) are included in the Santa Ana section, and down-to-the-west faults that form the eastern margin of the graben (Algodones fault) are include in the Algodones section. They assumed that one of |

| | |
|---|---|
| | these sections is a "master fault" that controls both sections, but they did not have enough subsurface data to support either scenario. |
| **Name comments** | **General:** This complex of numerous, generally north-trending normal faults near Santa Ana Mesa was first mapped in detail by Soister (1952 #1418). Kelley (1954 #1222) followed Soister's mapping closely in his compilation, and applied the name San Felipe fault zone to these structures. Later maps by Smith and others (1970 #1125), Kelley (1977 #1106), and Kelley and Kudo (1978 #1307) show similar fault patterns. Kelley (1977 #1106) named many of the more prominent structures in the zone, such as the Santa Ana, Luce, Cocida, and Algodones faults and the San Felipe graben. In their compilation, Wong and others (1995 #1155) used the name "San Felipe fault zone".<br><br>**Section:** The Santa Ana section includes the Santa Ana, Luce, and Cocida faults of Kelley (1977 #1106), the Tamaya fault of Personius (2002 #7526), and numerous smaller displacements, generally down-to-the-east faults that form the west flank of the San Felipe graben. This section also includes an unnamed, west-dipping fault of uncertain origin about 8 km west of the main fault zone (Pazzaglia and others, 1997 #7525). |

| **Physiographic province(s)** | BASIN AND RANGE <br>SOUTHERN ROCKY MOUNTAINS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault locations are good where faults cut volcanic rocks, but locations are poor in the less resistant Santa Fe Group rocks. Fault traces are from 1:24,000-scale maps of Pazzaglia and others (1997 #7525), Connell (1998 #7502), Chamberlin and others (1999 #7524), Personius (2002 #7526), and Kempter and others (2007 #7429). <P> |
| **Geologic setting** | The San Felipe fault zone is located in the western part of the Santo Domingo basin of the Rio Grande rift as defined by Smith and others (2001 #7438). The Santo Domingo basin links the en echelon Albuquerque and Española basins, and kinematic and paleostress evidence suggests that the basin functions as a relay that began to narrow in Plio-Pleistocene time (Minor and others, 2013 #7437). The fault zone forms a north-trending graben within the San Felipe volcanic field. Although Wong and others (1995 #1155) conclude that this graben is a minor sub-basin within |

| | |
|---|---|
| | the Rio Grande rift, the narrowing of the fault zone within the volcanic field indicates that the geometry of the fault zone may be in part controlled by volcanic activity (for example, van Wyk de Vries and Merle, 1996 #1422). <P> |
| **Length (km)** | This section is 44 km of a total fault length of 48 km. |
| **Average strike** | N5°E (for section) versus N1°E (for whole fault) |
| **Sense of movement** | Normal |
| **Dip** | 60°E–90°<br><br>*Comments:* An exposed section of the Luce fault along highway 44 west of Bernalillo yielded an east dip of 82° (Kelley, 1977 #1106). Connell (1998 #7502) reported east dips of 67–80° on the Luce fault in the Bernalillo 7.5-minute quadrangle, and Chamberlin and others (1999 #7524) reported east to southeast dips of 65–70° for the Cocida fault near Borrego Canyon in the Loma Creston quadrangle. Reported dips for the Santa Ana fault range from 65–80° toward the east or southeast (Chamberlin and others, 1999 #7524). Numerous fault exposures in Santa Fe Group rocks in the Santa Ana Pueblo quadrangle have dips of 45–85°E (Personius, 2002 #7526). <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | The Luce and other faults that cut the basalt flows of the San Felipe volcanic field are well preserved as escarpments covered by basalt talus. The Santa Ana fault and other faults that are only located in Santa Fe Group rocks are poorly expressed, except where they are marked in places by clastic dikes (Soister, 1952 #1418) or strongly cemented zones (Minor and Hudson, 2006 #7246). Soister (1952 #1418) and Kelley (1977 #1106) measured average displacements of 15–30 m in basalts on most structures in the fault zone, and as much as 90–120 m on larger structures such as the Luce fault. <P> |
| **Age of faulted surficial deposits** | Faults in the Santa Ana section offset the 2.4-2.6 Ma (Bachman and Mehnert, 1978 #1265; Smith and Kuhle, 1998 #1771) basalts of the San Felipe volcanic field and underlying Santa Fe Group sedimentary rocks. Soister (1952 #1418) describes offset of his early Pleistocene Mesita Alta gravel and surface, which overlies San Felipe basalt flows in several places. |

| | |
|---|---|
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* No detailed studies of the age of most recent movement have been conducted. However, 90–120 m of post-San Felipe basalt displacement on some structures in this fault zone indicates a history of recurrent fault movements that probably continued at least into the early Pleistocene. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Wong and others (1995 #1155) estimated slip rates of 0.01–0.04 mm/yr based on 90–120 m of displacement that has occurred on the Luce fault since deposition of the San Felipe basalt (2.4–2.6 Ma) and similar data. They also concluded that it is likely that some of the major faults within the San Felipe fault zone act as independent rupture segments, but could not rule out the possibility that some faults rupture together. |

## Sand Hill fault zone (Class A) No. 2039

**Last Review Date: 2016-06-28**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., and Jochems, A.P., compilers, 2016, Fault number 2039, Sand Hill fault zone, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:29 AM.**

| | |
|---|---|
| **Synopsis** | The down-to-the-east Sand Hill fault zone extends from about 9 km south of the Sandoval-Bernalillo County line, northward along the Ceja del Rio Puerco to the vicinity of Cañada de las Milpas. Very little is known about the Quaternary history of the Sand Hill fault zone other than that it cuts probable early Pleistocene sand and gravel of the upper Santa Fe Group and is buried by younger surficial deposits. This fault zone is one of several north-trending faults that form the active western boundary of the Rio Grande rift in the northern part of the Albuquerque-Belen basin. |
| **Name comments** | The Sand Hill fault zone was first named, mapped, and described by Bryan and McCann (1937 #1288), has subsequently been mapped in various degrees of detail by Wright (1946 #1427), Kelley and others (1976 #1380, fig. 19), and Kelley (1954 #1222; 1977 #1106), and has more recently been mapped in detail in the Arroyo de las Calabacillas (previously Sky Village SE), Benavidez Ranch, Cerro Conejo (previously Sky Village NE), and The Volcanoes 7.5-minute quadrangles (Cather and others, 1997 #1763; Koning and others, 1998 #7375; Thompson and others, 2009 #7460; Koning and Jochems, 2014 #7507). As originally mapped by Bryan and McCann (1937 #1288), |

| | |
|---|---|
| | the Sand Hill fault zone extended about 10 km along the western edge of the Llano de Albuquerque. Bryan and McCann (1937 #1288) and Wright (1946 #1427) mapped the southern end of the Sand Hill fault zone 3–5 km south of the Bernalillo-Sandoval County line; Bryan and McCann (1937 #1288) state that the fault is covered by Pleistocene and younger alluvium southward. Kelley (1977 #1106, p. 48) used stratigraphic arguments to extend the Sand Hill fault zone a minimum of 12 km further south. Similarly at the north end, Kelley and others (1976 #1380, fig. 19) and Kelley (1977 #1106, p. 48) extended the Sand Hill fault zone along a northeast-trending splay across the Llano de Albuquerque. Kelley (1977 #1106, p. 48) also suggests that some of the down-to-the-east displacement associated with the Sand Hill fault zone is taken up by the Garcia and Tenorio faults, which extend northward another 23 km along the western edge of the Llano. Mapping in the Arroyo de las Calabacillas 7.5-minute quadrangle (Cather and others, 1997 #1763) shows that the Sand Hill fault zone does not trend northeastward across the Llano de Albuquerque, but rather continues northward along the Ceja del Rio Puerco to the vicinity of Cañada de las Milpas in the Cerro Conejo quadrangle (Koning and others, 1998 #7375). Wright (1946 #1427) included in the Sand Hill fault zone a northwest-trending (N20°W) down-to-the-east fault that is 1–2 km east of the Sand Hill fault zone. However, the trend of this fault, Wright's detailed description of a thick sequence of tectonically-derived sediment on the downthrown block, and mapping in the Arroyo de las Calabacillas 7.5-minute quadrangle (Cather and others, 1997 #1763) all indicate that this eastern fault strand is distinct from the Sand Hill fault zone and thus is mapped as a separate structure (Calabacillas section of the Jemez-San Ysidro fault [2029c]) in this compilation. |

| **Sense of movement** | Normal |
| **Dip** | 54°–82° E.<br><br>*Comments:* Fault dips are from surface exposures (Wright, 1946 #1427, plate 8; Cather and others, 1997 #1763; Thompson and others, 2009 #7460; Koning and Jochems, 2014 #7507). <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | The fault is well expressed as linear breaks in slope in the eroded Santa Fe Group badlands below the western edge of the Llano de Albuquerque. Bryan and McCann (1937 #1288) noted that their northernmost strand has been injected by a sand dike that is more erosion resistant than the surrounding rocks; Wright (1946 #1427) stated that all strands of the Sand Hill fault are marked by sand dikes. In places, preferential cementation related to groundwater flow has formed prominent wall- or finger-like features in the fault zone (Mozley and Goodwin, 1995 #7508). No fault scarps on surficial deposits have been described, suggesting a lack of recency to the faulting. <P> |
| **Age of faulted surficial deposits** | The trace of the Sand Hill fault zone as originally mapped by Bryan and McCann (1937 #1288) lies entirely within the Upper Buff Member of the Santa Fe Formation, which is roughly correlative with the Ceja Formation of the Upper Santa Fe Group (Kelley, 1977 #1106; Hawley and others, 1991 #1302; Connell, 2008 #7506). In places the upper part of these deposits is early Pleistocene in age. No faulting of younger surficial deposits has been described. |
| **Historic earthquake** | |

| | |
|---|---|
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* The only deposits documented as offset by the Sand Hill fault zone are early Pleistocene to Pliocene in age. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* No detailed studies of fault offset or age of offset deposits are available; slip rate estimate is based on lack of fault scarps and low rates of slip on other faults in this part of the Rio Grande rift. |

# Quaternary Fault and Fold Database of the United States

**As of January 12, 2017, the USGS maintains a limited number of metadata fields that characterize the Quaternary faults and folds of the United States. For the most up-to-date information, please refer to the interactive fault map.**

## Santa Fe fault (Class A) No. 2123

**Last Review Date: 2015-12-21**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., and Jochems, A.P., compilers, 2015, Fault number 2123, Santa Fe fault, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:30 AM.**

| | |
|---|---|
| **Synopsis** | The Santa Fe fault forms the western margin of the Rio Grande rift in the central Albuquerque-Belen basin. The fault has been quite active in the Pliocene and early Pleistocene, based on offset of upper Santa Fe Group (Sierra Ladrones Formation) sediment. Other indirect evidence of Quaternary offset includes differences in the elevation of the "Ortiz surface" across the fault trace and the geometry of spring deposits found along the fault. However, no scarps on surficial deposits have been observed along the trace of the Santa Fe fault. |
| **Name comments** | The Santa Fe fault forms part of the western margin of the Rio Grande rift and the Albuquerque basin (Machette, 1982 #1401; Machette and McGimsey, 1983 #1024). The structure was originally named the Carrizo fault by Wright (1946 #1427), was later renamed the Santa Fe fault by Kelley and Wood (1946 #1379), and was included on subsequent compilations (Kelley, 1954 #1222; Kelley, 1977 #1106). The Santa Fe fault places Pliocene to early Pleistocene (Lozinsky and Tedford, 1991 #1399) sediment of the Sierra Ladrones Formation down-to-the-east against older rocks (Machette and McGimsey, 1983 #1024; Ricketts and Karlstrom, 2014 #7300). |

| | |
|---|---|
| | **Fault ID:** Fault no. 2 of Machette (1982 #1401), fault no. 1 of Machette and McGimsey (1983 #1024). |
| **County(s) and State(s)** | VALENCIA COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br>COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* No scarps on surficial deposits have been observed; the fault had been shown as dashed along most of its trace on published maps until mapping was completed along much of its trace by Ricketts and Karlstrom (2014 #7300). Fault location is taken from this 1:24,000 map. <P> |
| **Geologic setting** | The Santa Fe fault forms the western margin of the Rio Grande rift and the Albuquerque basin; this structure separates the rift from the edge of the Colorado Plateau to the west. <P> |
| **Length (km)** | 30 km. |
| **Average strike** | N4°E |
| **Sense of movement** | Normal |
| **Dip** | 45°–80° E<br><br>*Comments:* Dip data are from Wright (1946 #1427), Callender and Zilinski, (1976 #1289), Russell and Snelson (1994 #1186), and Ricketts and Karlstrom (2014 #7300). <P> |
| **Paleoseismology studies** | <P> |

| | |
|---|---|
| **Geomorphic expression** | No scarps have been recognized on surficial deposits along the Santa Fe fault, but the fault forms a bedrock escarpment along the northern half of its trace. <P> |
| **Age of faulted surficial deposits** | The Santa Fe fault offsets Pliocene to early Pleistocene (Lozinsky and Tedford, 1991 #1399) sediment of the Sierra Ladrones Formation down-to-the-east against older rocks (Machette and McGimsey, 1983 #1024; Ricketts and Karlstrom, 2014 #7300. Other indirect evidence of Quaternary offset includes differences in the elevation of the Pliocene (?) Ortiz surface across the fault trace (Kelley and others, 1976 #1380; Kelley, 1977 #1106, p. 28) and the geometry of spring deposits found along the fault (Callender and Zilinski, 1976 #1289). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* Timing estimate is based on offset of Pliocene-Pleistocene Sierra Ladrones Formation sediment (Machette and McGimsey, 1983 #1024; Ricketts and Karlstrom, 2014 #7300). <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* No detailed studies of fault offset or age of offset deposits are available; low slip-rate category is assigned based on about 30 m offset of 3.7-Ma basalt (Bachman and Mehnert, 1978 #1265) at the mouth of Arroyo Comanche (Kelley, 1977 #1106; Bachman and Mehnert, 1978 #1265). |

## unnamed fault of Bonita Canyon (Class B) No. 2144

**Last Review Date: 2016-04-22**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Machette, M.N., and Jochems, A.P., compilers, 2016, Fault number 2144, unnamed fault of Bonita Canyon, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:30 AM.**

| | |
|---|---|
| **Synopsis** | Fault scarp-like features have been mapped on the late Quaternary Twin Craters and El Calderon basalt flows of El Malpais lava field. The associated fault may represent reactivation of a bedrock fault that is concealed in Bonita Canyon, but which must juxtapose Precambrian rock on the west against Paleozoic rock on the east. However, similar mapped features within El Malpais lava field are considered by Levish and others (1992 #1715) to be related to volcanic processes. No detailed study of the fault has been conducted to confirm its origin or document the amount of vertical displacement that may be associated with it. Thus, the feature is herein considered to be of suspect origin. |

| | |
|---|---|
| **Name comments** | This fault was first mapped by Maxwell (1986 #1720). Levish and others (1992 #1715) characterized it a non-tectonic feature related to volcanic processes as part of a regional reconnaissance for a dam-hazards study. Levish and others (1992 #1715) referred to it as one of the faults in the Zuni-Bandera volcanic field. This fault forms a north-trending scarp (?) across the Twin Craters and El Calderon lava flows south of Bonita Canyon. The scarp is located at the south end of Cerritos de Jaspe (a prominent, west-facing ridge), which is just east of Bonita Canyon. |
| **County(s) and State(s)** | CIBOLA COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Trace from 1:62,500-scale geologic map of Maxwell (1986 #1720) combined with accurate placement using photogrammetric methods. <P> |
| **Geologic setting** | The fault is in Quaternary (undifferentiated) basalt flows according to the mapping of Maxwell (1986 #1720). It trends north on the basalts, and northwest up Bonita Canyon where it juxtaposes Precambrian rock on the west against Paleozoic rock on the east (Timmons and Cikoski, 2012 #7426). <P> |
| **Length (km)** | 9 km. |
| **Average strike** | N11°W |
| **Sense of movement** | Normal<br><br>*Comments:* Mapping by Maxwell (1986 #1720) and Timmons and Cikoski (2012 #7426) indicates that Paleozoic bedrock is down-dropped on the eastern side of the fault relative to Precambrian bedrock along a northern (concealed) extension of the fault. Conversely, where the fault crosses the El Calderon flow it appears to form a west-facing scarp. On the basis of this observation and similarity to other Cenozoic faults in the region, we infer that the fault has normal dip slip movement. <P> |

| | |
|---|---|
| **Dip Direction** | Unknown |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | The fault forms a 2-km-long north-trending scarp (?) on basaltic lava flows (Maxwell, 1986 #1720). Levish and others (1992 #1715) suggested that the fault is related to volcanic processes and is not of tectonic origin. No measurements of any vertical displacement have been made across the fault to confirm the amount or direction of possible movement. <P> |
| **Age of faulted surficial deposits** | Maxwell (1986 #1720) mapped the fault as offsetting the Twin Craters lava flow, dated at approximately 17_19 ka using radiocarbon and surface cosmogenic techniques (Laughlin and WoldeGabriel, 1997 #7425; Dunbar and Phillips, 2004 #7424). In addition, just south of New Mexico State Highway 53 the fault is mapped as crossing a small tongue of El Calderon flow, dated at 115–120 ka using paleomagnetic constraints (Cascadden and others, 1997 #7423). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* The fault scarp-like features are present on two Quaternary basalt flows dated at approximately 17–19 and 115–120 ka (Cascadden and others, 1997 #7423; Laughlin and WoldeGabriel, 1997 #7425; Dunbar and Phillips, 2004 #7424). <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* No measurement of offset across the fault has been reported. The fault does not appear to form a high or even moderate (>5 m) scarp on aerial photographs. Thus, it seems reasonable that slip rates associated with this suspect fault would be in the low slip-rate category (<0.2 mm/yr). |

## unnamed faults near Albuquerque Volcanoes (Class A) No. 2049

**Last Review Date: 2016-06-26**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

*citation for this record:* Personius, S.F., and Jochems, A.P., compilers, 2016, Fault number 2049, unnamed faults near Albuquerque Volcanoes, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:31 AM.

| | |
|---|---|
| **Synopsis** | Several unnamed north-trending normal faults are located near the Albuquerque Volcanoes. The basaltic volcanic field associated with the volcanoes is apparently confined in a broad graben, defined on the west by the down-to-the-east County Dump fault [2038] and on the east by the down-to-the-west East Paradise fault zone [2040]. Between these two flanking faults there is a series of smaller fault blocks and grabens. Most of these faults appear to be buried by basalt flows dated at about 155 ka. However, these faults can be mapped beneath the flows because most are marked by linear breaks in slope, indicating that preexisting fault scarps disrupted the flows during emplacement. The extent of some buried faults are also evident in high resolution aeromagnetic data. At least two faults are marked by more pronounced linear scarps that indicate small (1–2 m) post-basalt (155–218 ka) movements: a short down-to-the-east fault located between the East [2040] and West Paradise [2042] fault zones clearly offsets basalt in two places along the eastern edge of the volcanic field, and a longer north-trending down-to-the-west fault marked by small scarps in basalt bisects the volcanic field west of the West Paradise fault. This fault may have been the source of the 1978–1979 earthquake swarm near the Albuquerque Volcanoes. Latest movements on both the County Dump [2038] and East Paradise [2040] faults also post-date basalt emplacement. |
| **Name comments** | This group of structures is a series of north-trending normal faults on the east side of the Albuquerque Volcanoes. Some of these faults are included in the West Mesa fault zone of Wong and others (1995 #1155) and Hawley and Whitworth (1996 #1303). |
| **County(s) and State(s)** | SANDOVAL COUNTY, NEW MEXICO <br>BERNALILLO COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault traces from 1:24,000-scale maps of Connell and others (1998 #7490), Shroba and others (2003 #7459), and Thompson and others (2009 #7460). The locations of some traces beneath the volcanic field are based on high-resolution aeromagnetic data (U.S. Geological Survey and SIAL Geosciences Inc., 1997 #1722; Grauch and Millegan, 1998 #1721). <P> |

| | |
|---|---|
| **Geologic setting** | These structures are intrabasin faults in the central part of the Albuquerque-Belen basin of the Rio Grande rift. The broad graben that confines the Albuquerque Volcanoes volcanic field suggests that movement on some faults may be associated with magmatic activity. Recent seismicity may be associated with one of these intrabasin structures. An earthquake swarm in 1978–1979 near the southwestern margin of the volcanic field yielded a composite fault-plane solution with a preferred nodal plane striking N. 5° E. and dipping 74° W. (Jaksha and others, 1981 #1760). This fault plane projects to the surface very near the surface trace of an unnamed, 20 km long fault that lies 0.5 km east of the Albuquerque Volcanoes cinder cones. Northeast of the cinder cones, this fault is marked by small scarps on basalt that indicate post-basalt displacement. The County Dump fault [2038] is located between the surface trace of this fault and the surface projection of the earthquake 1978–1979 earthquake swarm, suggesting that the County Dump may sole into the fault at depth. <P> |
| **Length (km)** | 34 km. |
| **Average strike** | N5°W |
| **Sense of movement** | Normal |
| **Dip Direction** | E; W |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | Outside of the volcanic field, these faults are well expressed as eroded fault scarps on sediment of the upper Santa Fe Group and overlying surficial deposits. Within the Albuquerque Volcanoes volcanic field, these faults are marked by linear breaks in slope and minor fault scarps. Most breaks in slope along these faults appear to be preexisting scarps that disrupted the flow of basalt during eruptions to the west. At least two faults are marked by more pronounced linear scarps that indicate small post-basalt movements. Most of the fault traces in the volcanic field have been partly covered by eolian sand. <P> |
| **Age of faulted surficial deposits** | At least two of these faults offset the basalt of the Albuquerque Volcanoes volcanic field; these rocks have been dated by several methods at about 155–218 ka (Geissman and others, 1990 #1297; Peate and others, 1996 #1411; |

| | |
|---|---|
| | Singer and others, 2008 #7492). Most of the faults cut sediment of the upper Santa Fe Group and surficial deposits that predate emplacement of the basalts. |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | middle and late Quaternary (<750 ka)<br><br>*Comments:* At least two faults in this group offset the 155–218-ka basalts of the Albuquerque Volcanoes volcanic field, indicating probable late Pleistocene displacement. Most of the other faults have most recent movements that predate 155–218 ka. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Two of these structures offset the 155–218-ka basalts of the Albuquerque Volcanoes volcanic field by about 1–2 m, which suggests a low slip rate. |

## unnamed faults near Picuda Peak (Class A) No. 2041

**Last Review Date: 2016-06-26**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., and Jochems, A.P., compilers, 2016, Fault number 2041, unnamed faults near Picuda Peak, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:32 AM.**

| | |
|---|---|
| **Synopsis** | Near Picuda Peak there is a group of down-to-the-east and down-to-the-west, north trending normal faults that offset coarse gravels and underlying sands of the upper Santa Fe Group. Most of these faults trend to the northeast at their southern ends near Picuda Peak; further north, they trend generally north. Detailed mapping of the nearly complete exposures of the Santa Fe Group section in the Rincones de Zia show very closely spaced normal faults, most of which have displacements of only a few meters. These faults generally offset the uppermost coarse gravel of the Upper Santa Fe Group by a few tens of meters. |
| **Name comments** | This group of faults are herein named for their proximity to Picuda Peak. Some faults near Picuda Peak were previously described by Black and Hiss (1974 #1287) and Kelley (1977 #1106). These structures were mapped in detail by Manley (1978 #1404) in the Bernalillo NW 7.5-minute quadrangle and by Personius and others (2000 #1413) in the Loma Machete quadrangle. |

| | |
|---|---|
| **County(s) and State(s)** | SANDOVAL COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault traces are from 1:24,000-scale mapping of Manley (1978 #1404) in the Bernalillo NW quadrangle and Personius and others (2000 #1413) in the Loma Machete quadrangle. <P> |
| **Geologic setting** | Near Picuda Peak there is a group of down-to-the-east and down-to-the-west, north trending intrabasin faults near the northern margin of the Albuquerque-Belen basin in the Rio Grande rift. In previous publications, these faults were located near the crest of the Ziana anticline (Black and Hiss, 1974 #1287; Kelley and others, 1976 #1380; Kelley, 1977 #1106), but work by Personius and others (2000 #1413) indicates that opposing dips in the region that were thought to be the expression of a large fold may instead be related to intense normal faulting and block rotation. <P> |
| **Length (km)** | 10 km. |
| **Average strike** | N2°E |
| **Sense of movement** | Normal |
| **Dip** | 43–75° E., 47–87° W.<br><br>*Comments:* Numerous fault exposures indicate that these faults are usually steeply dipping (Personius and others, 2000 #1413). <P> |
| **Paleoseismology studies** | <P> |

| | |
|---|---|
| **Geomorphic expression** | Most faults form narrow topographic ridges and valleys that correlate with sense of fault displacement. Topographic expression is lost, but numerous fault exposures and juxtaposed bedrock mark these faults in the badlands of the Rincones de Zia. <P> |
| **Age of faulted surficial deposits** | The ages of offset deposits are poorly known, but the uppermost sand and gravel of the upper Santa Fe Group in this area are thought to be early Pleistocene in age (Personius and others, 2000 #1413). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* The unnamed faults near Picuda Peak offset early Pleistocene sediments of the upper Santa Fe Group a few tens of meters but do not appear to offset younger surficial deposits (Personius and others, 2000 #1413). <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Offsets of early Pleistocene gravels across individual faults are probably no more than 20–30 m. |

## unnamed faults near Star Heights (Class A) No. 2048

**Last Review Date: 2016-06-26**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., and Jochems, A.P., compilers, 2016, Fault number 2048, unnamed faults near Star Heights, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:32 AM.**

| | |
|---|---|
| **Synopsis** | This group of north-trending, mostly down-to-the-east normal faults offsets upper Santa Fe Group sediments, the Llano de Albuquerque, and younger piedmont deposits near the neighborhood of Star Heights. Individual faults have displaced upper Santa Fe Group sediments of a few tens of meters, 15–20 m of the Llano de Albuquerque, and 5–10 m in probable middle Pleistocene piedmont deposits. |
| **Name comments** | These north-trending normal faults include parts of the Star Heights fault of Kelley (1977 #1106) and Hawley and Whitworth (1996 #1303). Detailed mapping by Cather and others (1997 #1763), Personius and others (2000 #1413), and Thompson and others (2009 #7460) indicate that the Star Heights fault mapped by Kelley (1977 #1106) and Hawley and Whitworth (1996 #1303) includes parts of at least two separate faults, so this name has been abandoned. |
| **County(s) and State(s)** | BERNALILLO COUNTY, NEW MEXICO <br>SANDOVAL COUNTY, NEW MEXICO <br> |

| | |
|---|---|
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault traces from 1:24,000-scale mapping of Cather and others (1997 #1763), Personius and others (2000 #1413), and Thompson and others (2009 #7460) supplemented with additional photogrammetric analysis by Jochems. The locations of some fault traces are based on high-resolution aeromagnetic data (U.S. Geological Survey and SIAL Geosciences Inc., 1997 #1722; Grauch and Millegan, 1998 #1721). <P> |
| **Geologic setting** | These structures are intrabasin faults in the northern part of the Albuquerque-Belen basin of the Rio Grande rift. <P> |
| **Length (km)** | 18 km. |
| **Average strike** | N5°E |
| **Sense of movement** | Normal |
| **Dip** | 70° E.<br><br>*Comments:* Dip data are from Personius and others (2000 #1413). <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | These faults offset upper Santa Fe Group sediment, form broad scarps on the Llano de Albuquerque, and form steeper, smaller scarps on younger piedmont deposits. <P> |
| **Age of faulted surficial deposits** | These faults offset early Plio-Pleistocene upper Santa Fe Group sediment, the early Pleistocene Llano de Albuquerque, and younger piedmont deposits (Personius and others, 2000 #1413). The faulted piedmont deposits are characterized by well-developed (stage III) calcic soils, so they probably are middle Pleistocene in age. |

| | |
|---|---|
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | middle and late Quaternary (<750 ka)<br><br>*Comments:* Some of these structures offset the early Pleistocene Llano de Albuquerque 15–20 m and middle Pleistocene piedmont deposits 5–10 m; these data indicate a history of recurrent movement that, in some cases, possibly extend into the late Pleistocene. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Inferred low slip rate is based on presence of broad scarps on the Llano de Albuquerque that offset the surface 15–20 m. |

## unnamed faults of El Malpais lava field (Class B) No. 2146

**Last Review Date: 2016-04-22**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Machette, M.N., and Jochems, A.P., compilers, 2016, Fault number 2146, unnamed faults of El Malpais lava field, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:32 AM.**

| | |
|---|---|
| **Synopsis** | These three groups of suspect faults form numerous fissures and cracks in early Quaternary basalt flows of El Malpais lava field. They may include pressure ridges and collapsed lava tubes that give the expression of tectonic activity, but could be related to volcanic processes. Thus, these features are considered to be of suspect origin. No detailed studies of the features have been conducted to confirm their origin or document the amount of vertical displacement, if any, that may be associated with them. |
| **Name comments** | These faults were first mapped by Maxwell (1986 #1720); additional structures were mapped to the west by Baldridge and others (1989 #1741). Levish and others (1992 #1715), as part of a regional reconnaissance for a dam-hazards study, characterized them as non-tectonic features related to volcanic processes. Levish and others (1992 #1715) referred to the features as "Faults in the Zuni-Bandera volcanic field". The faults form four groups on El Malpais lava field. The southern group trends north across the North Plains, the main (longest) feature of which is named La Rendija. The southern extent of these faults is approximately 10 km south of the map area of Maxwell (1986 #1720). The northwestern group is comprised of two short north-northeast trending faults and associated |

| | |
|---|---|
| | fissure-like features located about 3 km south and southwest of Hoya de Cibola (Maxwell, 1986 #1720). The northeastern group is comprised of four short faults that trend north to northeast; they are located about 5 km southeast of Cerro Encierro. |
| **County(s) and State(s)** | CIBOLA COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | COLORADO PLATEAUS <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault traces are shown on 1:62,500-scale geologic map of Maxwell (1986 #1720) and a small-scale (approximately 1:400,000 scale) geologic map of Baldridge and others (1989 #1741). Extensions of the fault features west of Maxwell's mapping are shown on 1:100,000-scale geologic map of Anderson (1986 #1281). Fault traces were recompiled and digitized at 1:24,000 scale using photogrammetric methods. <P> |
| **Geologic setting** | These fault-like features are present on Quaternary (undifferentiated) basalt flows according to the mapping of Maxwell (1986 #1720). They trend north and northeast and may be related to westward directed extension or to the NE-trending Jemez lineament. Levish and others (1992 #1715) characterized the faults as non-tectonic features related to volcanic processes. <P> |
| **Length (km)** | 26 km. |
| **Average strike** | N7°E |
| **Sense of movement** | Normal<br><br>*Comments:* As mapped by Maxwell (1986 #1720), although most of the features are fissures that may not correspond to vertical displacement. <P> |
| **Dip Direction** | W; NW; SE |

| | |
|---|---|
| | *Comments:* As reported by Maxwell (1986 #1720). <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | The faults (?) form short north- and northeast-trending en echelon scarps (?), fissures, and open crevices in lava flows (Maxwell, 1986 #1720). Levish and others (1992 #1715) suggested that the faults are fissures, cracks, pressure ridges, and collapsed lava tubes that give the expression of tectonic activity, but are in fact related to volcanic processes. <P> |
| **Age of faulted surficial deposits** | Maxwell (1986 #1720) mapped the faults as having offset Quaternary basalts that have reported K-Ar ages as old as and 1.38±0.29 Ma and Ar-Ar ages as young as 0.593±0.086 Ma (Laughlin and West, 1976 #7420; Laughlin and others, 1993 #7421). These dates suggest that the older (undifferentiated) basalts flows (Qb) span the early to middle Quaternary. |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | undifferentiated Quaternary (<1.6 Ma)<br><br>*Comments:* The features are present on basalts flows (Qb) of early to possibly middle Quaternary age. However, Maxwell (1986 #1720) suggested that the southern group of features (La Rendija) is Holocene in age because the crevices are not filled with alluvium, thus suggesting very recent formation of the features. In addition, he suggested that the numerous small fault scarps (?) on unconsolidated alluvium at the eastern edge of North Plains are also young. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* No measurements of offset across the features have been reported. If the features are really faults of Holocene age (Maxwell, 1986 #1720) and have substantial (>10 m) offset, they could have a slip rate that exceeds 0.2 mm/yr. However, the features are formed on an early to middle Quaternary landscape; thus, the recurrence |

| | |
|---|---|
| | interval for accumulating stress prior to the most recent faulting (suspect) event could be 750 k.y. or more. It therefore seems reasonable that slip rates associated with these suspect faults would be in the lowest slip-rate category. |

## unnamed intrabasin faults west of the Rio Puerco (Class A) No. 2115

**Last Review Date: 2016-03-30**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., and Jochems, A.P., compilers, 2016, Fault number 2115, unnamed intrabasin faults west of the Rio Puerco, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:33 AM.**

| | |
|---|---|
| **Synopsis** | These intrabasin faults east of the Coyote Springs fault [2114] in the southwest Albuquerque basin of the Rio Grande rift are mostly expressed as short fault scarps in deposits of the upper Santa Fe Group Sierra Ladrones Formation; some have offsets of 3–20 m in middle Pleistocene alluvium. Most of the faults are partly to nearly completely buried by eolian sand. |
| **Name comments** | This group of structures consists of numerous short to relatively long, generally isolated, north-trending faults within the Belen sub-basin of the Albuquerque basin west of the Rio Puerco that were mapped by Machette (1982 #1401), Machette and McGimsey (1983 #1024), and Love and Young (1983 #1723). Some of these faults were previously mapped and named by Kelley (1977 #1106), including the east-down Gabaldon fault, the northern part of which was mapped by Lozinsky and Tedford (1991 #1339). |
| **County(s) and State(s)** | SOCORRO COUNTY, NEW MEXICO <br>VALENCIA COUNTY, NEW MEXICO <br> |

| | |
|---|---|
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:24,000 scale.<br><br>*Comments:* Fault traces compiled using photogrammetric methods and previous mapping of Machette and McGimsey (1983 #1024) at 1:250,000 scale and Lozinsky and Tedford (1991 #1339) at 1:24,000 scale. <P> |
| **Geologic setting** | These faults dip to the east and west, and form a broad zone within the active part of the Belen sub-basin of the Albuquerque basin, west of the Rio Puerco. The longest fault (~27 km) in this group of structures (Gabaldon fault of Kelley, 1977 #1106) is thought to be an east-down listric fault at depth based on 2D geophysical modeling and well data (Grauch and Connell, 2013 #7268). <P> |
| **Length (km)** | 22 km. |
| **Average strike** | N7°W |
| **Sense of movement** | Normal |
| **Dip Direction** | E; W<br><br>*Comments:* Grauch and Connell (2013 #7268) show the longest east-down fault in this group of structures as a relatively shallow listric fault based on 2D geophysical modeling and well data. <P> |
| **Paleoseismology studies** | <P> |
| **Geomorphic expression** | These faults are marked by subdued, discontinuously preserved scarps that are mostly covered by eolian sand within the western part of the Belen sub-basin. Machette and McGimsey (1983 #1024) measured offsets of 3–20 m in middle Pleistocene alluvium. <P> |

| | |
|---|---|
| **Age of faulted surficial deposits** | These faults offset lower Pleistocene sediment of the upper Santa Fe Group Sierra Ladrones Formation, and early and middle Pleistocene alluvium (Machette, 1978 #1223; Machette and McGimsey, 1983 #1024). |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | middle and late Quaternary (<750 ka)<br><br>*Comments:* No deposits younger than middle Pleistocene (150–750 ka) have been shown to be offset by these faults, but the 3–20 m offsets measured by Machette and McGimsey (1983 #1024) indicate a recurrent history of movement that in some cases probably extended into the late Pleistocene. <P> |
| **Recurrence interval** | |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* Low slip-rate category assigned based on offsets of 3–20 m of middle Pleistocene (150–750 ka) alluvium (Machette and McGimsey, 1983 #1024). |

U.S. Geological Survey - Earthquake Hazards Program

# Quaternary Fault and Fold Database of the United States

**As of January 12, 2017, the USGS maintains a limited number of metadata fields that characterize the Quaternary faults and folds of the United States. For the most up-to-date information, please refer to the interactive fault map.**

## Zia fault (Class A) No. 2046

**Last Review Date: 2015-04-13**

## Compiled in cooperation with the New Mexico Bureau of Geology & Mineral Resources

***citation for this record:*** **Personius, S.F., and Haller, K.M., compilers, 2015, Fault number 2046, Zia fault, in Quaternary fault and fold database of the United States: U.S. Geological Survey website, https://earthquakes.usgs.gov/hazards/qfaults, accessed 08/27/2025 11:33 AM.**

| | |
|---|---|
| **Synopsis** | The down-to-the-east Zia fault offsets Santa Fe Group sediment exposed in the Zia badlands, on the Llano de Albuquerque, and in younger Quaternary deposits. Upper Santa Fe Group sediment may have been offset about 60 m across the Zia fault since early Quaternary time. |
| **Name comments** | The Zia fault is one of several north-trending normal faults named by Kelley (1977 #1106) in the Zia badlands in the northern part of the Albuquerque-Belen basin. Galusha (1966 #1296), G.O. Bachman (unpublished mapping, 1975) and Manley (1978 #1404) mapped the northern end of the Zia fault in the Sky Village NE and Bernalillo NW quadrangles, respectively. Galusha (1966 #1296) and Manley (1978 #1404) used the name Rincon fault in the Bernalillo NW quadrangle, but we retain the name Zia fault herein due to apparent common usage in recent publications (Wong and others, 1995 #1155; Hawley and Whitworth, 1996 #1303). Recent mapping (Hawley and Whitworth, 1996 #1303; Cather and others, 1997 #1763; Connell, 2008 #7454) extends the Zia fault much further south than the original trace of the fault as mapped by Kelley (1977 #1106). |

| | |
|---|---|
| **County(s) and State(s)** | BERNALILLO COUNTY, NEW MEXICO <br>SANDOVAL COUNTY, NEW MEXICO <br> |
| **Physiographic province(s)** | BASIN AND RANGE <br> |
| **Reliability of location** | Good<br>Compiled at 1:100,000 scale.<br><br>*Comments:* Fault trace from Manley (1978 #1404) in the Bernalillo NW quadrangle, G.O. Bachman (unpubl. mapping, 1975) in the Sky Village NE quadrangle, Cather and others (1997 #1763) in the Sky Village SE quadrangle, and unpublished air photo mapping by the compiler (1997) in the Sky Village NE, Sky Village SE, and Volcano Ranch quadrangles, all recompiled at 1:100,000 scale on a topographic base map. The fault location is also evident in high-resolution aeromagnetic data (U.S. Geological Survey and SIAL Geosciences Inc., 1997 #1722; Grauch and Millegan, 1998 #1721). <P> The southern trace of the Zia fault is open to interpretation. Cather and others (1997 #1763) mapped the Zia fault as a queried trace with a southward strike along the eastern margin of the Sky Village SE (now Arroyo de las Calabacillas) 7.5-minute quadrangle. However, the compiler used the mapping of Hawley and Whitworth (1996 #1303), airphoto analysis (S.F. Personius, unpubl. mapping, 1997), and geophysical data (U.S. Geological Survey and SIAL Geosciences Inc., 1997 #1722; Grauch and Millegan, 1998 #1721) to infer a more southwestward trace of the Zia fault across the Sky Village SE quadrangle. The latter trace is used in the compilation because the fault appears to have better topographic expression, and thus may have younger movement. <P> |
| **Geologic setting** | The Zia fault is one of several down-to-the-east intrabasin faults in the northern part of the Albuquerque-Belen basin. <P> |
| **Length (km)** | 32 km. |
| **Average strike** | N15°E |
| **Sense of movement** | Normal |

| | |
|---|---|
| **Dip Direction** | E |
| **Paleoseismology studies** | Site 2046-1. Referred to as the Zia trench site is located near the southern rim of Ceja de-Rio Jemez (the northern limit of the Llano de Albuquerque geomorphic surface). McCalpin and Harrison (2001 #6924) excavated three trenches at this site in order to better observe the stratigraphy. The middle trench crosses the steepest, highest part of the fault scarp and reveals evidence for at least 5 faulting events. Displacement in these events ranged from 0.6 to 2.6 m, with an average of 1.3 m. The study includes two independent age estimates from soil-carbonate accumulation and luminescence ages. Soil-carbonate age estimates are preferred because the thermoluminescence ages (56–416 ka) were deemed unreliable because all dates are in an inverted stratigraphic order. The soils in the upper 3 m of the trench required 10–32 k.y. to form, and the strong soils at the base of the trench required an additional 32 k.y. <P> |
| **Geomorphic expression** | The Zia fault is well exposed in Santa Fe Group sediment in the Zia badlands north of the Llano de Albuquerque. Farther south, the fault forms broad, dissected fault scarps across the Llano de Albuquerque and on younger surficial deposits. <P> |
| **Age of faulted surficial deposits** | Manley (1978 #1404) described minor (0.5 m) offset of middle or upper (?) Pleistocene alluvium by the Zia fault in the Bernalillo NW quadrangle. Kelly (1997 #1106) estimated approximately 60 m of throw in Upper Santa Fe Group sediment (Pliocene to early Pleistocene) across the Zia fault. In most places, the Zia fault offsets the early Pleistocene Llano de Albuquerque surface and middle (?) Pleistocene surficial deposits. |
| **Historic earthquake** | |
| **Most recent prehistoric deformation** | latest Quaternary (<15 ka)<br><br>*Comments:* McCalpin and Harrison (2001 #6924) conclude that the most recent surface rupture at the trench site occurred about 11 ka as inferred from soil-carbonate age estimates. Furthermore, the most recent event is older than the Holocene unconformity that occurred about 2,380–2,740 cal. yr BP. <P> |
| **Recurrence interval** | 10–21 k.y. (<119 ka) |

| | |
|---|---|
| | *Comments:* McCalpin and Harrison (2001 #6924) base their estimate of long-term average recurrence by assuming five events have occurred since the formation of buried soils 5 and 6, which have a soil-carbonate age estimate of greater than 63 ka and an optically stimulated luminescence (OSL) age of 119 ka. McCalpin and Harrison (2001 #6924) suggest that if the most recent event occurred at 11 ka, then the four preceding recurrence cycles spanned 52–108 k.y., which results in an average recurrence interval of 10–21 k.y. |
| **Slip-rate category** | Less than 0.2 mm/yr<br><br>*Comments:* The five events inferred from the middle trench have a cumulative down-to-the-east vertical displacement of 6.5 m, which occurred over the past 63-119 ka. McCalpin and Harrison (2001 #6924) suggest that the resulting average long-term vertical displacement rate is 0.055–0.1 mm/yr. |

Name: 2029ab Jemez-San Ysidro fault (dip 50)
Region: USGS 2014 New Mexico
Category:Fault
Fault Mechanism: Normal
Magnitude Scale: Moment Magnitude
Probability of Activity: 0.60000000
Deterministic Magnitude: 7.09

Fault Profile Parameters:

| Dip1 | Dip2 | Depth1 | Depth2 | Depth3 |
|---|---|---|---|---|
| 90 | 50 | 0 | 0.001 | 15 |

# PROBABILISTIC ANALYSES

# APPENDIX D.1
# SUMMARY OF PROBABILISTIC CHARACTERISTICS

## Appendix D.1 Probabilistic Characteristics of Quaternary Faults and Folds Capable of Generating a PGA of 0.05g or Greater

| Name of Faults | ID Number | Age of Most Recent Prehistoric Deformation (ya)[1] | Probability of Activity | Dip[2] (Degrees) | Maximum Seismogenic Depth[2] (km) | Rate of Activity[2] (mm/yr) | MCE[3,4] |
|---|---|---|---|---|---|---|---|
| Intrabasin faults on the Llano de Albuquerque | 2121 | <750,000 | 1 | 60 | 15 | 0.02 | 7.5 |
| Jemez-San Ysidro fault (Jemez and San Ysidro sections)[(4)] | 2029ab | <1,600,000 | 1 | 35 (0.2)<br>50 (0.4)<br>65 (0.2) | 15 | (4) | 7.09 |
| Jemez-San Ysidro fault (Calabacillas section)[(4)] | 2029c | <15,000 | 1 | 35 (0.2)<br>50 (0.4)<br>65 (0.2) | 15 | (4) | 6.83 |
| Mesa Prieta faults | 1985 | <1,600,000 | 0.5 | 60 | 15 | 0.02 | 6.3 |
| Nacimiento fault (northern and southern sections)[(4)] | 2002ab | <1,600,000 | 1 | 35 (0.2)<br>50 (0.4)<br>65 (0.2) | 15 | (4) | 7.3 |
| Sand Hill fault zone | 2039 | <1,600,000 | 0.5 | 60 | 15 | 0.02 | 6.9 |
| Santa Fe fault | 2123 | <1,600,000 | 0.5 | 60 | 15 | 0.02 | 6.8 |
| unnamed faults near Albuquerque Volcanoes | 2049 | <750,000 | 1 | 60 | 15 | 0.02 | 6.9 |
| unnamed faults of El Malpais lava field | 2146 | <1,600,000 | 0.5 | 60 | 15 | 0.02 | 6.7 |

1) Years ago
2) Number in parentheses represents weights for each parameter
3) The middle number is the magnitude of the Maximum Credible Earthquake as calculated by Wells and Coppersmith (1994), an additional minimum and maximum of MCE +0.3 and MCE -0.3 are entered for each model in the analysis of the fault to account for standard error in their equation.
4) The parameters included in the EZ Frisk program from the USGS Hazard mapping used for analysis.

DETERMINISTIC FRACTILES

PLOTTING PARAMETERS
  Period at which to plot PGA: 0.0001

CALCULATIONAL PARAMETERS
  Fault Seismic Sources -
    Maximum inclusion distance           :   1000 km
    Down dip integration increment       :   1 km
    Horizontal integration increment     :   1 km
    Number rupture length per earthquake :   4
  Subduction Interface Seismic Sources -
    Maximum inclusion distance           :   1000 km
    Down dip integration increment       :   5 km
    Horizontal integration increment     :   20 km
    Number rupture length per earthquake :   1
  Subduction Slab Seismic Sources -
    Maximum inclusion distance           :   1000 km
    Down dip integration increment       :   5 km
    Horizontal integration increment     :   20 km
    Number rupture length per earthquake :   1
  Area Seismic Sources -

```
    Maximum inclusion distance           :   1000 km
    Vertical integration increment       :   3 km
    Number of rupture azimuths           :   3
    Minimum epicentral distance step     :   0.5 km
    Maximum epicentral distance step     :   10 km
  Gridded Seismic Sources -
    Maximum inclusion distance           :   400 km
    Default number of rupture azimuths   :   10
    Maximum distance for default azimuths :   20 km
    Minimum distance for one azimuth     :   70
    Use binned calcuations if possible   :   true
    Bins per decade in distance (km)     :   20
  All Seismic Sources -
    Magnitude integration step           :   0.1 M
    Apply magnitude scaling              :   NO

# APPENDIX D
# Technical Memorandum – Frost Depth Analysis

# *Technical Memorandum*

| | | | |
|---|---|---|---|
| To: | Rio Grande Resources Ltd. | From: | Jason Andrews P.E.,<br>Larry Coons P.E. |
| Company: | Rio Grande Resources Ltd. | Date: | October 9, 2025 |
| EA No.: | 111360 | | |
| Re: | Mt. Taylor Uranium Mine<br>- Frost Depth Analysis | | |

## 1.0 INTRODUCTION

This technical memorandum provides the frost depth analysis and results to support the design of the proposed expanded disposal cell. The radon barrier should be located below the calculated frost depth to protect against freeze-thaw impacts.

## 2.0 FROST DEPTH ANALYSIS

The frost depth penetration into the final reclamation cover (cover) for the proposed expanded disposal cell was determined using the procedure adopted by the U.S. Department of Energy and accepted by the Nuclear Regulatory Commission (DOE, 1989). The depth of freezing into the cover (depth of frost penetration) is governed by the local climate, soil material and soil moisture content expected during the operational life of the cover. The procedure used includes a computational procedure to predict frost depth which was initially proposed by Berggren (1943). Smith and Rager (2002) apply these previous studies to determine an adequate thickness of a protective soil layer to protect underlying compacted soil. The freezing depth was calculated for a 200-year recurrence interval (0.5% probability of occurrence in any given year).

### 2.1 Analyzed Final Reclamation Cover Configuration

The following cover system is proposed to overlay the clay layer (radon barrier) and was analyzed for frost penetration. The proposed cover system is presented on Figure D-1.

- 12-inches of rock mulch (erosion protection) consisting of gravel mixed with onsite soil used as Soil Cover.
- 28-inches of onsite soil cover (biointrusion and frost protection.)

## 2.2 Input parameters

Calculations

- ***Step 1 Determine freeze-index parameters.***
  Fifty years of historic temperature data consisting of maximum and minimum daily air temperatures was obtained from Grants, New Mexico Municipal Airport for the main data source, additional alternative data sources included the on-site meteorological station at the Mt. Taylor Mine, and the historical weather records of San Mateo, New Mexico. The historic climate data sources and data used in the calculations are presented in Attachment D1.

  The degree day calculation was used to compute the duration of freeze. The duration of freeze is defined as length of time in days that the cumulative degree day is below freezing (Smith and Rager, 2002). The degree day, defined as the mean daily temperature minus 32 degrees Fahrenheit (freezing point of water) (Smith and Rager, 2002) was calculated and presented in Attachment D1. The cumulative degree-days versus the days in the freeze year are plotted. The cumulative degree day plots are provided in Attachment D2.1 and are used to determine the duration of freeze. The selection of points for the duration of freeze calculation is provided in Attachment D2.2

- ***Step 2 Determine surface temperature correction factor.***
  A surface correction factor, N, is applied to the daily temperature data used to correct for difference between air temperature and ground temperature. A surface correction factor of 0.7 for bare soil was chosen from Table 1 of Smith and Rager (2002).

- ***Step 3 Determine thermal properties.***
  Soil thermal properties: thermal conductivity, heat capacity, and latent heat of fusion are products of empirical relationships between the dry unit weight (pcf) and gravimetric moisture content (%). For the purpose of these calculations, the relationships presented by Bianchini and Gonzalez (2012) were used. The thermal conductivity, volumetric heat capacity and latent heat of fusion for each of the soil types for the respective layer are presented in Table 1 below. The thermal ratio and fusion parameter for each of the soil types are presented in Table 2 below. The parameters presented in Tables 1 and 2 were calculated with the following equations from Bianchini and Gonzalez (2012) presented below.

**Thermal conductivity equations:**

$$K_f = \frac{0.076(10)^{0.013\gamma_d} + 0.032(10)^{0.013\gamma_d * w}}{12}$$

$$K_u = \frac{(0.07\log(w) + 0.04)(10)^{0.01\gamma_d}}{12}$$

Where:

$K_u$ = Thermal Conductivity of unfrozen soil
$K_f$ = Thermal Conductivity of frozen soil
$\gamma_d$ = soil dry unit weight
$w$ = soil water content as percentage

**Volumetric heat capacity equation:**

$$C_{avg} = \gamma_d(c + 0.75\frac{w}{100})$$

Where:

$C_{avg}$ = Average volumetric heat capacity
$\gamma_d$ = soil dry unit weight
$w$ = soil water content as percentage
$c$ = specific heat of the soil solids

**Volumetric latent heat of fusion equation:**

$$L = 144\gamma_d\frac{w}{100}$$

Where:

L= Volumetric latent heat of fusion
$\gamma_d$ = soil dry unit weight
$w$ = soil water content as percentage

**Thermal ratio equation:**

$$\alpha = \frac{v_0}{v_s}$$

Where:

$\alpha$ = Thermal Ratio
$v_0$ =absolute value of the difference between the mean annual temperature below the ground surface and 32° F.
$v_s$ =the term is computed in two different ways in relation to problem analysis.

**Term $v_s$ equation:**

$$v_s = \frac{nF}{t}$$

Where:

$n$ = conversion factor from air index to surface index
$F$ = air-freezing index

$t$ = length of the freezing season

**Fusion parameter equation:**

$$\mu = \frac{C}{L} v_s$$

Where

$C$= Volumetric Heat Capacity
$L$ = Volumetric latent heat of fusion

**Table 1 – Thermal Properties**

| Layer | Depth (Inches) | Optimum Dry Density (PCF) | Water Content (%) | Dry Density (85% of Proctor) (PCF) | Thermal Conductivity Kf (BTU/ Ft hr °F) | Thermal Conductivity Ku (BTU/ Ft hr °F) | Average Thermal Conductivity (1/2*( Ku+Kf)) (BTU/ Ft hr °F) | Volumetric Heat Capacity (Cavg) (BTU/ft$^3$ °F) | Latent Heat of Fusion (BTU/ft$^3$) |
|---|---|---|---|---|---|---|---|---|---|
| Mulch | 12 | 115 | 10 | 97.8 | 0.83 | 0.87 | 0.85 | 23.9 | 1407.6 |

**Table 2 – Thermal Parameters**

| Layer | Average Temperature (°F) | Freeze Index (Degree-Day) | Duration (Days) | Vs | Vo | Thermal Ratio | Fusion Parameter |
|---|---|---|---|---|---|---|---|
| Mulch | 63.1 | 927.5 | 173 | 3.8 | 31.1 | 8.25 | 0.06 |
| Soil Cover | 63.1 | 927.5 | 173 | 3.8 | 31.1 | 8.25 | 0.06 |

- ***Step 4 Determine 200-year recurrence interval.***
  NRC, 10 CFR Appendix A to Part 40, Criterion 6, Paragraph 1 states that the design life should be 1,000 years when reasonably achievable and at a minimum, 200 years. As discussed in Smith and Rager (2002) the use of a 200-year recurrence interval for frost depth analysis meets the requirements of 40 Code of Federal Regulations Part 40. Mean annual temperature was calculated for each year in the data set. The mean annual temperature was plotted and projected to develop the mean minimum temperature for 200 years using the method presented in Smith and Rager (2002). The results of this are presented in Attachment D3.1.

  In addition to the mean annual temperature, the frost index and duration of freeze were calculated for each year in the data set as stated in Step 1. These data were plotted and projected to develop the 200-year maximum frost index and duration of freeze using the method presented in Smith and Rager (2002). The results are presented in Attachments D3.2 and D3.3, respectively.

- ***Step 5 Determine freezing depth.***
  To determine the frost depth of 200-year recurrence interval the method for manual solution of the Modberg Equation presented in Bianchini and Gonzalez (2012) was applied using the parameters calculated in Step 4 to determine the depth of the freezing front inside of the cover system. The depth of the freezing front is presented in Attachment D4.

## 3.0 CONCLUSIONS

The frost penetration depth into the final cover for the 200-year recurrence interval was calculated to be 28 inches. The total thickness of material over the radon barrier is proposed to be 40 inches. Thus, the radon barrier is not anticipated to experience any impacts from freezing.

| Re: | Mt. Taylor Uranium Mine – Radon Cover Design and Analyses | | |

## 1.0 INTRODUCTION

This technical memorandum presents the results of modeling of emanation of radon-226 from the top surface of the proposed cover over the expanded disposal cell. These results comprise radon attenuation modeling based on the proposed cover design, and cover materials.

The cover system design consists of a three-layer cover system over contaminated soils, with a total thickness of approximately 52 inches (4.33 feet) as shown on Figure 4-1. The final cover system will consist of the following layers from top to bottom.

- 12 inches of rock mulch cover for erosion protection.
- 28 inches of onsite in-situ soils for bio intrusion and frost protection.
- 12 inches of clay layer to minimize infiltration and emanation of radon gas

For the radon emanation modeling, the rock mulch layer was included as the uppermost modeled cover layer because the Uranium Mill Tailings Cover Calculator was run with four layers: contaminated materials, clay radon barrier, in-situ soil, and rock mulch.

The radon emanation modeling shows that the planned cover system reduces the rate of radon emanation to values below the Nuclear Regulatory Commission (NRC) limit of 20 picocuries per square meter per second (pCi/$m^2$-sec) averaged over the entire expanded disposal cell.

## 2.0 DESCRIPTION OF MODEL AND INPUT VALUES

Radon emanation calculations for the cover system were made using the Wise Uranium Project Uranium Mill Tailings Cover Calculator, which implements the RADON model described in NRC Regulatory Guide 3.64 (NRC, 1989). The calculator evaluates one-dimensional radon-222 diffusion from a radium-226 source through layered cover materials. The calculator was run using metric units with four model layers: contaminated materials, clay radon barrier, in-situ soil, and rock mulch. The key input parameters include layer thickness, radium-226 activity concentration, radon emanation coefficient, porosity, long-term moisture content, and the calculated radon diffusion coefficient. The input parameters and values used in the model are outlined below.

### 2.1 Radium Activity Concentrations

Radium-226 activity values used in the model were taken from Radiological Characterization Reports by AVM Environmental Services, Inc. (AVM) for the Windblown Area, Ore Pad Area, and Mine Compound (AVM 2023), for the Treatment Ponds (AVM 2024), and for the North Controlled Area (AVM 2025). The radium-226 activity values used in the model are summarized below. Attachment E-1 includes pages extracted from the AVM reports used to calculate representative radium activities for the model.

**Windblown Area (WA):** The representative radium-226 activity value for contaminated soils within the WA north of the mine site was estimated from a static gamma radiation survey performed by AVM (2023) on May 17 and May 31, 2023. Attachment E-1.1 includes Table 2 from the AVM report illustrating the results of the survey, and Figure 1 from the AVM report illustrating the location of the WA. From a total of 12 survey locations using data for the "Bare 2x2 Nal Detector", a mean activity value of 9.8 pCi/g Ra-226 is estimated.

**Ore Pad Area (OPA):** The representative radium-226 activity value for contaminated soils within the OPA was estimated from a static gamma radiation survey performed by AVM (2023) on May 31, 2023. Attachment E-1.1 includes Table 2 from the AVM report illustrating the results of the survey, and Figure 1 from the AVM report illustrating the location of the OPA. From a total of 5 survey locations using data for the "Bare 2x2 Nal Detector", a mean activity value of 431.6 pCi/g Ra-226 is estimated.

**Mine Compound Area (MCA):** The representative radium-226 activity value for contaminated soils within the MCA was estimated from a static gamma radiation survey performed by AVM (2023) from May 18 through May 31, 2023. Attachment E-1.1 includes Table 2 from the AVM report illustrating the results of the survey, and Figure 1 from the AVM report illustrating the location of the MCA. From a total of 20 survey locations using data for the "Bare 2x2 Nal Detector", a mean activity value of 13.1 pCi/g Ra-226 is estimated.

**Pond Area (PA):** The representative radium-226 activity value for contaminated soils within the PA was estimated from a static gamma radiation survey performed by AVM (2024) from October 18, 2023. Attachment E-1.2 includes Table 1 from the AVM report illustrating the results of the survey, and Figure 1 from the AVM report illustrating the location of the PA. From a total of 40

survey locations using data for the "Bare 2x2 Nal Detector", a mean activity value of 4.8 pCi/g Ra-226 is estimated.

**North Controlled Area (NCA):** The representative radium-226 activity value for contaminated soils within the NCA was estimated from a static gamma radiation survey performed by AVM (2025) from September 19 through December 12, 2024. Attachment E-1.3 includes Table 2 from the AVM report illustrating the results of the survey, and Figure 1 from the AVM report illustrating the location of the NCA. From a total of 47 survey locations using data for the "Bare 2x2 Nal Detector", a mean activity value of 47.1 pCi/g Ra-226 is estimated.

Ra-226 activity concentration is a required model input. For the purposes of modeling radon emanation, the arithmetic mean radium-226 concentration value from the five distinct source areas (WA, OPA, MCA, PA, and NCA) is approximately 101 pCi/g. The updated Uranium Mill Tailings Cover Calculator run used a Ra-226 activity concentration of 115 pCi/g for the contaminated materials layer. For this to be a reasonable assumption in the assessment of radon flux from the cover, it is recommended that the materials from the OPA be placed at the base of the disposal cell because the OPA materials have the highest mean Ra-226 activity concentration (431.6 pCi/g).

## 2.2 Radion Emanation Coefficient

Radon emanation coefficient is a required model input. For all modeled layers, including the contaminated materials and cover materials, a radon emanation coefficient of 0.35 was used. This is the conservative default value used in the Uranium Mill Tailings Cover Calculator.

## 2.3 Density and Porosity

Attachment E-2 includes laboratory testing data for the cover layer materials. While material density of the cover layers is not a direct model input, material placement and performance density affects the porosity and long-term moisture model input values. The general textures of the contaminated materials to be consolidated into the expanded disposal cell consist of some variable percentages of silt, clay and sand. As such, a density of 100 lb/cf (1.60 g/cc) was assumed for contaminated materials below the cover. For the 12-inch layer of radon barrier clay on top of the waste, a value of 99 lb/cf (1.59 g/cc) was used which is equivalent to 90 percent of the standard Proctor dry density of the clay sample from EA-BSB04 collected from Borrow Area A-B in January 2025. For the in-situ frost protection soil layer above the radon barrier, a value of 94 lb/cf (1.51 g/cc) was used which is equivalent to 85 percent of the mean standard Proctor dry density of samples EA-BSB04 (sand), EA-BSC12 (sandy clay), and EA-BSC09 (silty clay) collected from Borrow Area A-B in January 2025. The same density of 94 lb/cf (1.51 g/cc) was used for the upper rock mulch layer as the soil matrix of the rock mulch layer is anticipated to be the same as, or similar to, the in-situ soil layer.

Porosity is a required model input. Porosity values for the waste material, the in-situ soil layer, and the rock mulch layer are not very sensitive to calculation of radon flux in the model, and the values can range +/- 20 percent individually with only a +/-10 percent change in radon flux. In contrast, radon flux calculated by the model is sensitive to porosity of the radon barrier. A similar

range of +/- 20 percent change in radon barrier porosity can change the calculated radon flux value to zero (with a lower porosity value), or can double the calculated radon flux (with a higher porosity value). A typical porosity value for the mixed sand, silt and clay of 0.35 was assumed for the waste materials. The porosity of the radon barrier clay layer was estimated from the compaction test report for sample EA-BSC09 (silty clay). From the compaction test report, a void ratio of 0.62 can be determined, and an associated porosity of 0.38 is calculated. For the in-situ soil layer and upper rock mulch layer, a porosity of 0.35 is assumed.

## 2.4 Long-Term Moisture Content

Long-term moisture content of the cover layers is a required model input. The long-term moisture contents for the frost protection layer and rock mulch layer were assumed to be 6% based on the NRC guidance (1989). While the long-term moisture contents of both the waste materials and the radon barrier are sensitive to calculation of radon flux, the long term moisture content of the radon barrier is particularly sensitive to calculation of radon flux. The long-term, 15-bar, moisture content of the radon barrier clay layer was determined to be 15.1 percent from EA-BSC09 (silty clay) collected from Borrow Area A-B in January 2025 (Attachment E-2). This value represents a sample of the material remolded to 90 percent of the standard Proctor density. The long term, 15-bar, moisture content for the contaminated material below the radon barrier was also assumed to be 15.1 percent since the materials are below the depth of influence from evapotranspiration.

## 2.5 Radion Diffusion Coefficient

The radon diffusion coefficient was calculated by the Uranium Mill Tailings Cover Calculator based on the material properties and moisture content for each layer. The calculated diffusion coefficients used in the updated model are 1.69E-07 $m^2/s$ for the contaminated materials, 4.62E-07 $m^2/s$ for the clay radon barrier, and 2.01E-06 $m^2/s$ for both the in-situ soil layer and rock mulch layer. The lower the diffusion coefficient value, the lower the resulting rate of radon emanation through the layer.

# 3.0 RESULTS

The input values and updated results from the Uranium Mill Tailings Cover Calculator are summarized in Table E-1. The model output is provided in Attachment E-3.

The updated radon emanation model results presented in Table E-1 show that the cover system reduces the calculated radon-222 flux from a bare source flux of 42.10 $pCi/m^2/s$ to 13.99 $pCi/m^2/s$ at the top of the cover system. The calculated total cover radon retention is 66.77 percent. The final calculated radon flux is below the NRC allowable emanation limit of 20 $pCi/m^2/s$ averaged over the disposal cell.

# 4.0 RADON SENSITIVITY ANALYSIS CALCULATIONS

## 4.1 Mathematical Framework

The sensitivity calculations in Table 4.3 were generated using the one-dimensional, steady state radon diffusion model from U.S. NRC Regulatory Guide 3.64 ("Calculation of Radon Flux Attenuation by Earthen Uranium Mill Tailings Covers").
The governing differential equation for radon 222 diffusion in a porous medium is:

$$D\frac{d^2C}{dx^2} - \lambda C + \frac{R\rho E\lambda}{n} = 0$$

Where:

- $C$= radon-222 concentration in the pore space $\left(\text{pCi/cm}^3\right)$
- $D$= effective radon diffusion coefficient ($\text{m}^2/\text{s}$)
- $\lambda$= radon-222 decay constant ($2.1 \times 10^{-6}\ \text{s}^{-1}$)
- $R$= Ra-226 activity concentration (pCi/g)
- $\rho$= dry density $\left(\text{g/cm}^3\right)$
- $E$= radon emanation coefficient (dimensionless)
- $n$= total porosity (dimensionless)
- $x$= depth (m)

Radon flux at any interface is computed using Fick's Law:

$$J = -10^4 \cdot D \cdot n\frac{dC}{dx}$$

For the multilayer system (Waste to Clay Barrier to Undisturbed Soil to Rock Mulch), continuity of concentration and flux is enforced at each interface. The resulting system of hyperbolic functions (, ) is solved numerically using a matrix solution in the WISE Uranium Project cover calculator. A key intermediate parameter is the diffusion length :

$$l = \sqrt{\frac{D}{\lambda}}$$

## 4.2 Base Input Parameters

Baseline parameters were established from site geotechnical data and conservative design assumptions.

Layer 1 – Contaminated Waste (source):

- $R = 115$ pCi/g
- $\rho = 1.60$ g/cm$^3$
- $n = 0.35$
- $E = 0.35$
- $D_1 = 1.69 \times 10^{-7}$ m$^2$/s
- Thickness ≈ 197 in (5.0 m; treated as effectively infinite)

Layer 2 – Compacted Clay Radon Barrier:

- $\rho = 1.59$ g/cm$^3$
- $n = 0.38$
- $D_{\text{clay}} = 4.62 \times 10^{-7}$ m$^2$/s
- $l_{\text{clay}} = \sqrt{\frac{4.62\times10^{-7}}{2.1\times10^{-6}}} \approx 0.469$ m

Layer 3 – Undisturbed Soil Cover:

- $\rho = 1.51$ g/cm$^3$
- $n = 0.35$
- $D_{\text{soil}} = 2.01 \times 10^{-6}$ m$^2$/s
- $l_{\text{soil}} = \sqrt{\frac{2.01\times10^{-6}}{2.1\times10^{-6}}} \approx 0.978$ m

Layer 4 – Rock Mulch:

- $\rho = 1.51$ g/cm$^3$
- $n = 0.35$
- $D_{\text{mulch}} = 2.01 \times 10^{-6}$ m$^2$/s
- Thickness = 12 in = 0.305 m (constant for all cases)

## 4.3 Sensitivity Case Configurations (Table 4.3 of main report)

Each case modifies layer thicknesses or diffusion coefficients and is then solved with the same numerical framework. The flux values below are direct model outputs.

- **Case 1 – Base Design**
    - Clay: 12 in (0.305 m)
    - Soil: 28 in (0.711 m)
    - Diffusion: baseline $D_{\text{clay}}, D_{\text{soil}}, D_{\text{mulch}}$
    - Note: Clay provides the strongest attenuation due to its short diffusion length.
    - **Calculated surface flux:** $J = 13.99$ pCi/m$^2$/s
- **Case 2: Reduced Undisturbed Soil Cover**
    - Clay: 12 in (0.305 m)
    - Soil: 20 in (0.508 m)
    - Diffusion: baseline values
    - Note: Shorter soil path length reduces attenuation above the clay barrier.
    - **Calculated surface flux:** $J = 16.21$ pCi/m$^2$/s
- **Case 3: Increased Undisturbed Soil Cover**
    - Clay: 12 in (0.305 m)
    - Soil: 36 in (0.914 m)
    - Diffusion: baseline values
    - Note: Longer soil path increases decay opportunity before radon reaches the surface.
    - **Calculated surface flux:** $J = 12.08$ pCi/m$^2$/s
- **Case 4 – Reduced Clay Barrier**
    - Clay: 9 in (0.229 m)
    - Soil: 28 in (0.711 m)
    - Diffusion: baseline values
    - Note: Removing 3 in of low diffusivity clay has a larger impact than removing 8 in of soil because clay controls the sharpest attenuation.
    - **Calculated surface flux:** $J = 17.62$ pCi/m$^2$/s
- **Case 5: Higher Diffusion Coefficient (1.5 times)**
    - Geometry: 12 in clay, 28 in soil, 12 in mulch
    - Adjusted diffusion:

- $D'_{\text{clay}} = 1.5 \times 4.62 \times 10^{-7} = 6.93 \times 10^{-7}$ m$^2$/s
- $D'_{\text{soil}} = 1.5 \times 2.01 \times 10^{-6} = 3.015 \times 10^{-6}$ m$^2$/s
- $D'_{\text{mulch}} = 3.015 \times 10^{-6}$ m$^2$/s

  - Note: Simulates drier, more diffusive long term conditions; clay diffusion length increases to .
  - **Calculated surface flux:** $J = 18.74$ pCi/m$^2$/s

- **Case 6: Lower Diffusion Coefficient (0.75 times)**
  - Geometry: 12 in clay, 28 in soil, 12 in mulch
  - Adjusted diffusion:
    - $D'_{\text{clay}} = 0.75 \times 4.62 \times 10^{-7} = 3.465 \times 10^{-7}$ m$^2$/s
    - $D'_{\text{soil}} = 0.75 \times 2.01 \times 10^{-6} = 1.508 \times 10^{-6}$ m$^2$/s
    - $D'_{\text{mulch}} = 1.508 \times 10^{-6}$ m$^2$/s
  - Note: Simulates well-compacted, moist conditions that restrict gas transport.
  - **Calculated surface flux:** $J = 11.34$ pCi/m$^2$/s

### 4.4 Results of Sensitivity Assessment

All sensitivity cases, including reduced clay thickness, reduced soil thickness, and increased diffusion, remain below the regulatory limit of 20 pCi/m$^2$/s. The results are shown in Table E-2. The analysis confirms that the optimized 52 inch cover provides a robust margin of safety for radon attenuation under plausible variations in geometry and material properties.

Notes:
1 - See Figure 4-1.
2 – Required model assumption for all materials.
3 – Exit radon flux calculated by the Uranium Mill Tailings Cover Calculator at the top of each modeled layer.
4 – The soil matrix of the rock mulch layer is similar to, or the same as, the in-situ soil layer and thus governs the properties of the rock mulch layer.
5 – Mean values from compaction test reports for samples EA-BSC09 (silty clay), EA-BSC12 (sandy clay), and EA-BSB04 (sand) from Borrow Areas A-B (Attachment E-2). Porosity values are assumed for mixed sand, silt, and clay.
6 - Long term moisture content NRC (1989).
7 – Input values for clay radon barrier from compaction test report for sample EA-BSC09 (Attachment E-2) assuming a density of 90% of maximum standard Proctor density. The long-term 15-bar moisture content from the soil water characteristic curve (SWCC) for sample EA-BSC09 (Attachment E-2)
8 – The contaminated materials below the cover are assumed to be 5 meters (16.4 feet) thick. Soil properties of the waste materials are assumed to be characteristic of a mixed sand, silt, and clay with a porosity of 0.35, dry density of 100 pcf (1.60 $g/cm^3$), Ra-226 activity of 115 pCi/g, emanation coefficient of 0.35, and long-term moisture content of 15.1 percent.

**Table E-2 – Results of Sensitivity Analysis**

| Case | On-Site Soil Cover Thickness (in) | Clay Barrier Thickness (in) | Radon Diffusion Coefficient Assumption | Surface Flux (pCi/m²/s) |
|---|---|---|---|---|
| Appendix F base design | 28 | 12 | Appendix F design value | 13.99 |
| Reduced on-site soil cover | 20 | 12 | Appendix F design value | 16.21 |
| Increased on-site soil cover | 36 | 12 | Appendix F design value | 12.08 |
| Reduced clay barrier | 28 | 9 | Appendix F design value | 17.62 |
| Higher diffusion coefficient | 28 | 12 | 1.5 × Appendix F value | 18.74 |
| Lower diffusion coefficient | 28 | 12 | 0.75 × Appendix F value | 11.34 |

|---|---|---|---|
| **To:** | Rio Grande Resources | **From:** | Jason Andrews, PE<br>Olu Iwakun, P.Eng |
| **Company:** | Rio Grande Resources | **Date:** | August 5, 2026 |
| **EA No.:** | 111360 | | |
| **Re:** | Statistical Comparison of 2018–2025 Climate Data to Historical and Regional Design-Support Datasets – Mt. Taylor / San Mateo Area | | |
| **Cc:** | | | |

## 1.0 INTRODUCTION

The Mt. Taylor Uranium Mine is in the San Mateo area of west-central New Mexico, at an elevation of approximately 7,400 feet above mean sea level. An on-site automated weather station has collected continuous meteorological data since October 2017. This memorandum uses complete calendar years (January through December 2018–2025) for annual statistical comparisons.

This memorandum presents a statistical comparison of recent climate conditions (2018–2025) to the broader historical record used for Mt. Taylor disposal cell design support near San Mateo and Grants, New Mexico. The analysis focuses on three climate variables critical to long-term cover performance and design: annual precipitation, mean annual temperature, and the Air Freezing Index (AFI). Unless otherwise noted, references to AppD3-1, AppD3-2, and AppD3-3 refer to Appendices D3-1 through D3-3 of the 2025 *Mt. Taylor Disposal Cell Design Report* prepared by Engineering Analytics, Inc. for Rio Grande Resources, Project No. 111360. The primary goal is to assess whether the regional meteorological data and design-basis climate inputs, including the Gallup 1981–2010 precipitation normal, the AppD3-1 temperature comparison dataset, the AppD3-2 AFI comparison dataset, and the NCEI NM3422 long-term temperature trend record is statistically consistent with the recent, onsite, climate period (2018–2025).

### 1.1 Data Sources

Recent site climate data (2018–2025) were obtained from the San Mateo station dataset. Long-term regional precipitation context is based on the Gallup Municipal Airport 30-year climate normal, which provides the most appropriate standardized annual precipitation baseline for the Mt. Taylor area because it is a published NCDC/NCEI climate normal, covers the standard 1981–2010 climatological averaging period, represents the same regional semi-arid precipitation regime, and provides a complete annual normal where the NM3422 Grants dataset does not provide a complete annual precipitation series suitable for this comparison. Rice Park SNOTEL is used separately for high-elevation snowpack, snow water equivalent (SWE), winter precipitation, frost penetration, accumulated freezing index (AFI), snowmelt infiltration, and Rio San Jose Integrated Hydrologic Model (RSJIHM) calibration. These datasets are complementary but not interchangeable.

### 1.2 Analytical Approach

This analysis is structured to determine whether the complete San Mateo on-site climate record for 2018–2025 is consistent with the historical and regional datasets used to support the Mt. Taylor disposal cell design basis. The comparison is not intended to prove that separate datasets are identical or interchangeable. Instead, it evaluates whether recent site observations fall within the range of conditions represented by the applicable design-support datasets. This distinction is important because each dataset serves a different technical purpose: Gallup provides the long-term annual precipitation normal, AppD3-1 and AppD3-2 from EA's 2025 *Mt. Taylor Disposal Cell Design Report* provide historical temperature and AFI comparison datasets, NCEI NM3422 provides long-term regional temperature trend context, and Rice Park SNOTEL supports winter hydrology, snowpack, SWE, frost penetration, AFI calibration, snowmelt infiltration, and RSJIHM calibration.

The analytical approach combines descriptive statistics, targeted hypothesis testing, and visual diagnostics. Descriptive statistics summarize the San Mateo annual record for precipitation, mean annual temperature, and AFI using the mean, standard deviation, range, and observed minimum and maximum values. The San Mateo summary statistics are then compared with the appropriate design-support benchmarks: the Gallup 1981–2010 annual precipitation normal, AppD3-1 temperature values, the historical-only AppD3-2 AFI values, and NCEI NM3422 long-term temperature trend data. A one-sample t-test is used for San Mateo precipitation against the Gallup annual normal, while Welch's two-sample t-tests are used for mean annual temperature and AFI because those comparisons involve samples with unequal sizes and variances. The results are interpreted in terms of design relevance, with emphasis on whether the recent site record supports continued use of the existing precipitation, temperature, AFI, water-balance, and frost-penetration assumptions.

## 2.0 SITE DESCRIPTION, CLIMATE SETTING, AND DATA SOURCES

### 2.1 Site Setting and Regional Climate Context

The Mt. Taylor Uranium Mine disposal cell area is in the San Mateo Mountains of Cibola County, New Mexico, within the southern Colorado Plateau physiographic province at an elevation of approximately 7,400 feet above mean sea level. The climate is semi-arid continental, characterized

by low humidity, high solar radiation, large diurnal temperature swings, and a pronounced North American Monsoon precipitation pattern during July through September.

For historical context, this analysis references NCEI station NM3422 (Grants, New Mexico), regional precipitation normals from Gallup Municipal Airport, Rice Park SNOTEL winter hydrology data, and summary statistics from the Mt. Taylor Mine design report. Gallup is used as the regional mean annual precipitation baseline because it is the nearest appropriate standardized 30-year climate normal with a published annual precipitation value, represents the same broad semi-arid regional precipitation setting, and provides a defensible long-term reference where NM3422 does not provide a complete annual precipitation series suitable for this comparison. Rice Park is used for SWE, snowpack, winter precipitation, AFI, frost penetration, snowmelt infiltration, and RSJIHM calibration because those processes cannot be evaluated from the Gallup climate normal.

## 2.2 Regional Climate Overview

Mean annual temperature in the region ranges from approximately 48°F to 54°F depending on elevation and period of record. NCEI Station NM3422 at Grants, New Mexico, records a mean annual temperature of approximately 49.93°F for the 1975–2025 period, with a statistically significant warming trend of +0.033°F per year ($R^2 = 0.37$, $p < 0.001$). Precipitation is bimodal, with a dominant monsoon contribution in summer and a secondary winter precipitation season. The 1981–2010 climate normal at Gallup Municipal Airport (NCDC Station 293422) gives an average annual precipitation of 11.65 inches.

The Gallup normal is used in this memo for annual precipitation comparison because it is a published 30-year climatological normal rather than a short-term site record, and it therefore provides a stable regional benchmark for evaluating whether the 2018–2025 San Mateo record is anomalous. Its use is limited to annual precipitation context and statistical comparison; it is not used to characterize site-specific storm intensity, snowpack, SWE, or winter hydrologic processes.

## 2.3 Instrumentation and Station Description

The on-site San Mateo weather station provides automated recording of temperature (maximum, minimum, and mean), precipitation (tipping bucket rain gauge), wind speed and direction, and derived parameters including heating and cooling degree days. Data collection began in October 2017. Only complete calendar years (2018–2025) are used for annual analyses.

# 3.0 HYDROLOGIC AND THERMAL CHARACTERIZATION

This section characterizes the site's hydrologic regime, thermal profile, and precipitation frequency using data from the San Mateo station, NCEI NM3422 (Grants, NM), and regional frequency analyses.

## 3.1 Monthly Precipitation and Evapotranspiration

Site monthly precipitation exhibits a pronounced summer monsoon pattern, with precipitation elevated during May through September and strongest during July through September. July has the highest San Mateo monthly average of 2.05 inches. Potential evapotranspiration (PET), estimated via the Thornthwaite method, peaks in July at 5.26 inches. On an annual basis, PET substantially exceeds precipitation; monthly PET exceeds precipitation during the primary warm-season moisture-demand period, while several winter months show small monthly precipitation surpluses. Table 3-1 and Figure 3-1 present the monthly comparison.

**Table 3-1 Monthly Precipitation and Potential Evapotranspiration (PET) Summary**

| Month | Precipitation (in) | Potential ET (in) | Monthly Deficit (in) |
|---|---|---|---|
| January | 0.38 | 0.00 | −0.38 |
| February | 0.26 | 0.16 | −0.10 |
| March | 0.48 | 0.69 | 0.21 |
| April | 0.28 | 1.76 | 1.48 |
| May | 0.71 | 3.15 | 2.44 |
| June | 0.94 | 4.74 | 3.80 |
| July | 2.05 | 5.26 | 3.21 |
| August | 1.71 | 4.70 | 2.99 |
| September | 1.45 | 3.46 | 2.01 |
| October | 0.86 | 1.83 | 0.97 |
| November | 0.59 | 0.57 | −0.02 |
| December | 0.30 | 0.13 | −0.17 |
| **Annual Total** | **10.01** | **26.45** | **16.44** |

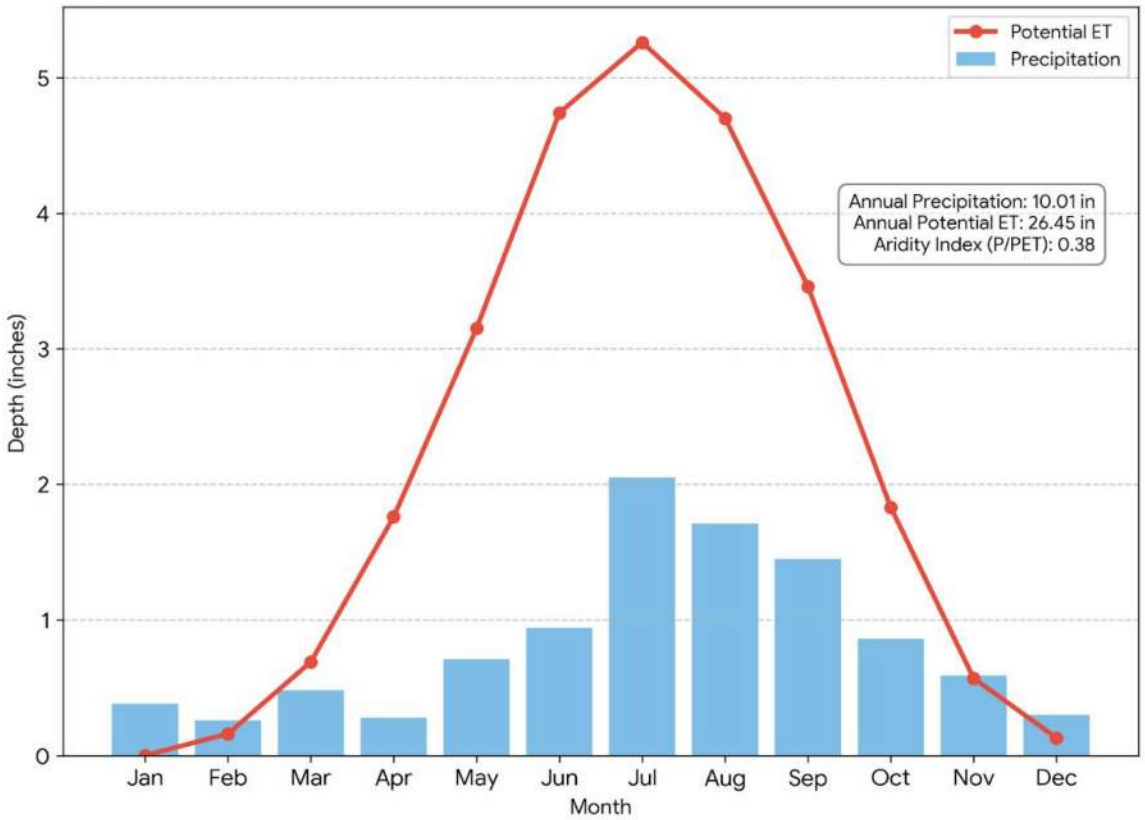

**Figure 3-1 Monthly Precipitation and Potential Evapotranspiration**

## 3.2 Precipitation Depth-Duration-Frequency

Table 3-2 and Figure 3-2 summarize precipitation depth-duration-frequency data for the site, using regional frequency analysis. Table 3-2 lists precipitation depths for various return periods (2 to 100 years) and durations (1-hour to 24-hour), showing that longer return periods correspond to higher rainfall amounts; for example, the 24-hour depth for a 2-year event is 1.2 inches, increasing for rarer storms. These values inform stormwater management design.

**Table 3-2 Precipitation Depth-Duration-Frequency Summary (inches)**

| Return Period (years) | 1-Hour | 6-Hour | 12-Hour | 24-Hour |
|---|---|---|---|---|
| 2 | 0.72 | 0.94 | 1.05 | 1.20 |
| 5 | 0.96 | 1.19 | 1.32 | 1.50 |
| 10 | 1.14 | 1.39 | 1.53 | 1.74 |
| 25 | 1.39 | 1.66 | 1.82 | 2.06 |
| 50 | 1.58 | 1.88 | 2.04 | 2.31 |
| 100 | 1.78 | 2.10 | 2.27 | 2.56 |

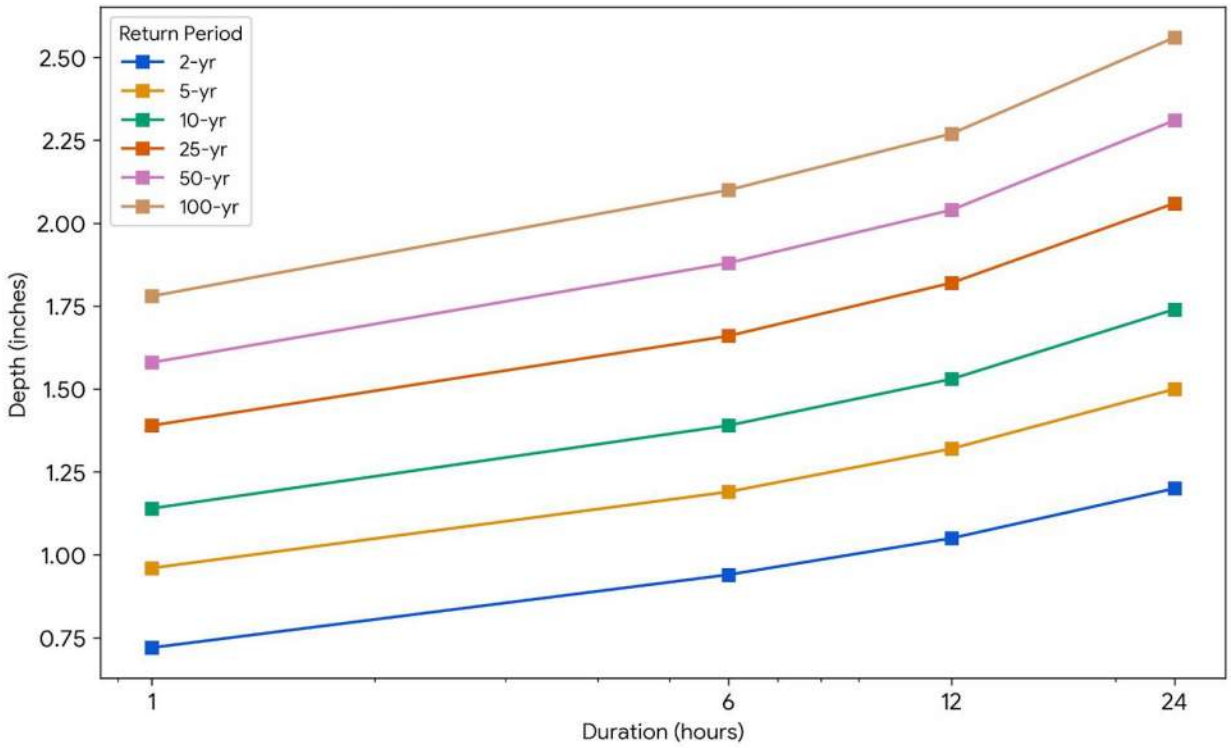

**Figure 3-2 Precipitation Depth-Duration-Frequency (DDF) Curves**

Figure 3-2 compares precipitation depths across durations and return periods. The curves show increasing depth with both longer duration and rarer recurrence intervals, including the 100-year, 24-hour storm depth of 2.56 inches. These values support stormwater conveyance, erosion protection, and run-on/runoff control design.

## 3.3 Cumulative Water Balance

Figure 3-3 shows cumulative water-year precipitation of 10.01 inches and PET of 26.45 inches, producing an annual moisture deficit of 16.44 inches. The aridity index of 0.38 classifies the site as semi-arid under the UNESCO definition (AI < 0.50) and confirms that annual evapotranspiration demand substantially exceeds precipitation.

**Table 3-3 Annual Water Balance Summary**

| Component | Value (inches/year) | Source |
|---|---|---|
| Annual Precipitation (P) | 10.01 | San Mateo station 2018–2025 monthly means |
| Estimated Annual PET | 26.45 | Thornthwaite method (site temperatures at 35°N) |
| Annual Moisture Deficit (PET − P) | 16.44 | Calculated |
| Aridity Index (P/PET) | 0.38 | Calculated (semi-arid classification) |
| Gallup Annual Normal Precipitation | 11.65 | NCDC 1981–2010 normals |

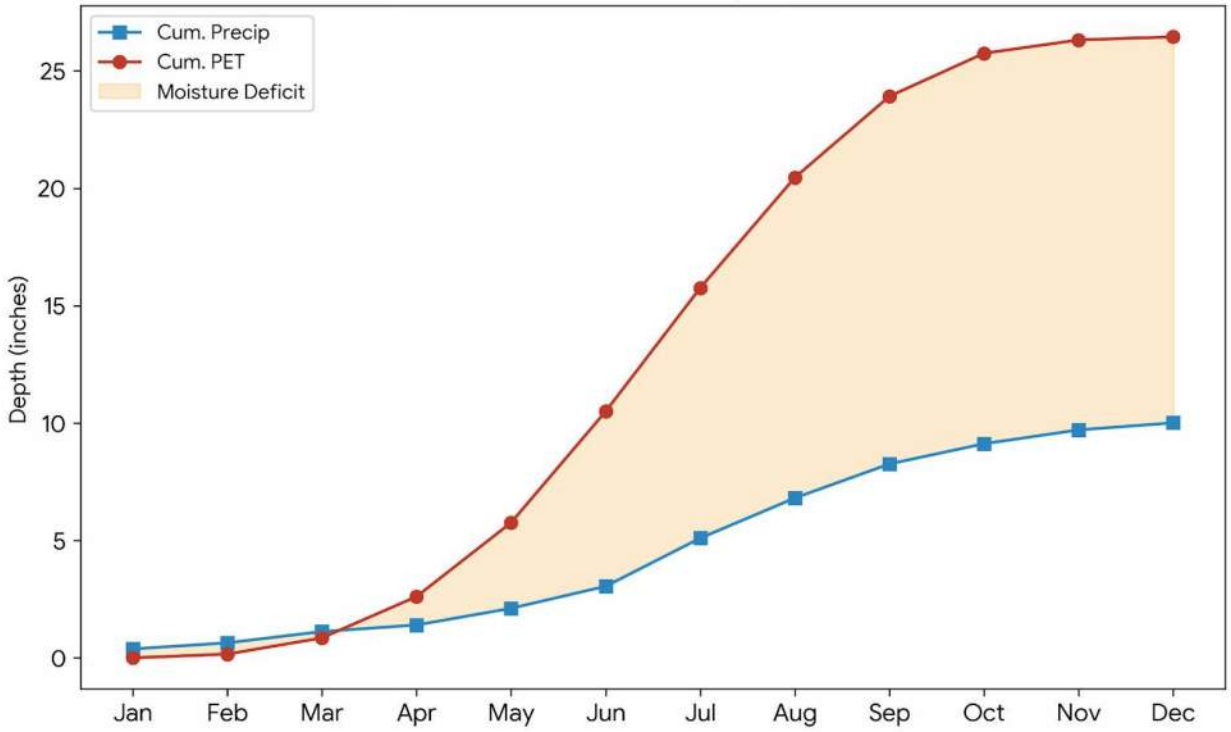

**Figure 3-3 Cumulative Water Year Precipitation and PET Analysis**

Table 3-3 summarizes the annual water-balance components supporting Figure 3-3. Annual precipitation is based on San Mateo monthly means, while PET is estimated using the Thornthwaite method. The annual precipitation total of 10.01 inches is substantially lower than the estimated annual PET of 26.45 inches, resulting in a persistent annual moisture deficit. Together, Table 3-3 and Figure 3-3 confirm the site's semi-arid hydrologic setting and support use of evapotranspiration-based cover-system design assumptions

### 3.4 Regional Temperature Trend

Analysis of NCEI Station NM3422 (Grants, NM) mean annual temperature data for 1975–2025 reveals a statistically significant warming trend of +0.033°F per year ($R^2 = 0.37$, $p < 0.001$), corresponding to approximately 1.7°F of total warming over 51 years. The San Mateo on-site temperatures (2018–2025) plot consistently above the NCEI station values, reflecting station exposure, instrumentation, and local microclimate differences between the Grants station and the mine site. This regional warming trend provides context for interpreting the site-to-historical temperature comparison in Section 6. The time series and trend line are presented in Figure 3-4.

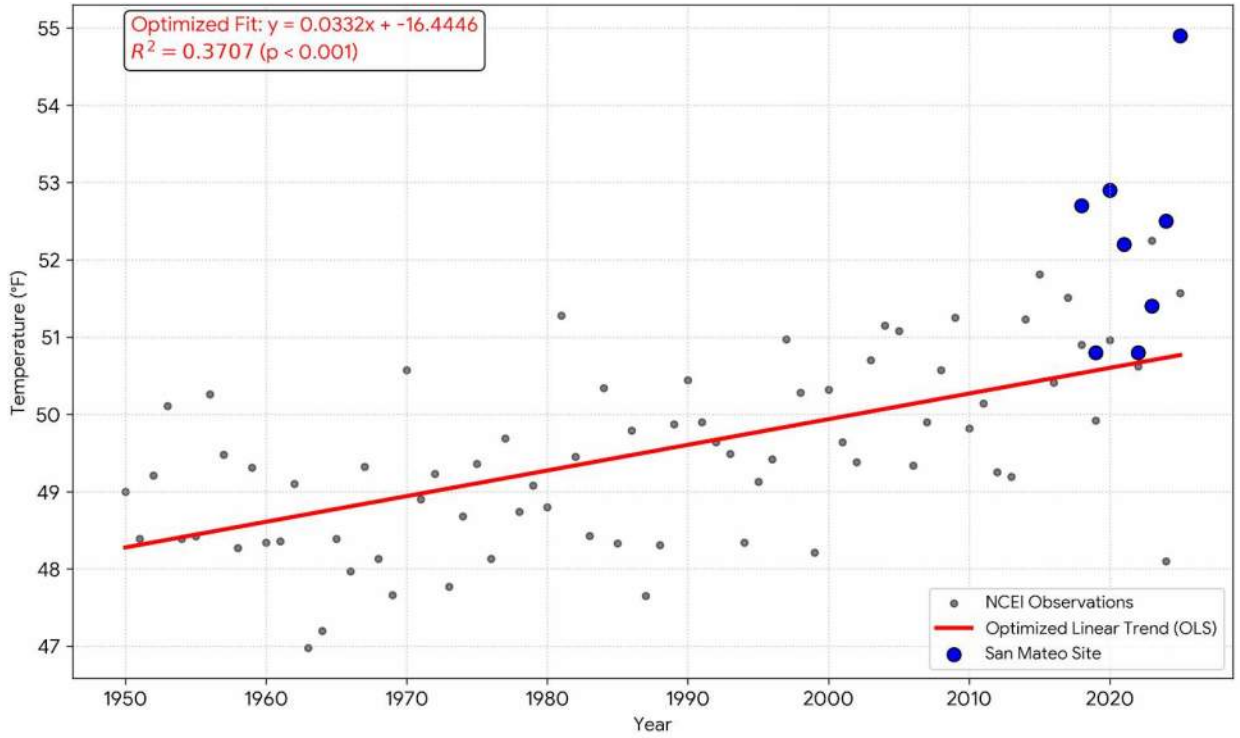

**Figure 3-4 Mean Annual Temperature Trend (NCEI Station NM3422, Grants, NM)**

## 4.0 METHODOLOGY AND STATISTICAL FRAMEWORK

The comparative analysis uses a multi-tiered statistical framework designed to answer the regulatory and engineering question raised in review: whether the recent San Mateo site record is consistent with the climate datasets used to support Mt. Taylor design assumptions. Each method below is included to show what was calculated, why it matters, and how the result informs use of the Gallup precipitation normal, the AppD3 temperature and AFI appendix datasets from EA's 2025 *Mt. Taylor Disposal Cell Design Report*, and Rice Park winter hydrology information.

## 4.1 Descriptive Statistics

For each applicable dataset, the mean, standard deviation, variance, minimum, and maximum were computed where the underlying annual values were available. These statistics matter because they show both the central tendency and the spread of the record; a recent site mean that falls within normal historical variability supports continued use of the existing design-basis climate inputs.

$$\bar{x} = \frac{\sum x_i}{n}, s = \sqrt{\frac{\sum (x_i - \bar{x})^2}{n-1}}$$

Where a dataset is represented only by a published climatological normal, such as the Gallup annual precipitation normal, the analysis uses that value as the long-term regional mean rather than treating it as a full annual distribution.

## 4.2 Hypothesis Testing Framework

Mean annual temperature and AFI were compared between the recent period (2018–2025) and the historical baseline (1975–2024) using Welch's two-sample t-test, which does not assume equal variances or equal sample sizes. This method is appropriate because the historical and recent datasets have unequal variances and sample sizes. The test statistics are:

$$t = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}},$$

with $\bar{x}_1, s_1, n_1$ and $\bar{x}_2, s_2, n_2$ denoting the means, standard deviations, and sample sizes for the recent and historical periods, respectively. A Welch-type t-test (unequal variances) is appropriate given the differing standard deviations. Effect sizes are summarized using Cohen's d, defined as:

$$d = \frac{\bar{x}_1 - \bar{x}_2}{s_{\text{pooled}}},$$

Where $s_{\text{pooled}}$ is the pooled standard deviation. Effect sizes were interpreted using conventional screening thresholds of $|d| \approx 0.2$, 0.5, and 0.8 for small, medium, and large effects, respectively. These thresholds were used only to describe practical magnitude; statistical decisions were based on the two-tailed p-values at $\alpha = 0.05$. The tests are complemented by visual diagnostics (boxplots, histograms, and time series) to help reviewers see whether the recent San Mateo record plots within the historical or regional comparison range.

San Mateo precipitation is compared to the Gallup NCDC 30-year normal using a one-sample t-test because Gallup provides the applicable long-term regional annual precipitation mean and the available historical precipitation baseline is represented by a climatological normal rather than a complete annual distribution. Gallup is used for this test because it supplies a published, standardized, 30-year annual precipitation benchmark for the same regional semi-arid climate setting, whereas NM3422 lacks a complete annual precipitation series for direct annual comparison

and Rice Park is intended for SWE and winter hydrology applications. For a one-sample test, the test statistics are:

$$t = \frac{\bar{x} - \mu_0}{s/\sqrt{n}},$$

where $\bar{x}$is the sample mean, $s$is the sample standard deviation, $n$is the sample size, and $\mu_0$is the hypothesized population mean. The null hypothesis $H_0$is that the recent mean equals the historical mean; the alternative $H_A$is that they differ (two-sided test). Degrees of freedom are $n - 1$, and p-values are obtained from the t distribution.

This method is applicable because the historical precipitation dataset is represented by a single climatological normal, not a full distribution. This test evaluates whether the San Mateo mean differs from the long-term regional mean.

### 4.3 Recurrence-Interval and Extremal Analysis

AFI values were ranked within the historical distribution to determine exceedance probabilities and recurrence intervals. This analysis is included because frost penetration and cover-system performance are controlled by infrequent severe freezing years rather than average annual conditions alone; therefore, AFI return-period estimates provide the design context for comparing recent San Mateo observations with the conservative design-basis AFI.

### 4.4 Non-Parametric Considerations

A Mann–Whitney U test is typically used for precipitation when comparing two full distributions. However, because the historical precipitation dataset is represented by a single normal (not a full annual series), the one-sample t-test is the appropriate method for this analysis.

**Table 4-1 San Mateo Station Annual Climate Summary (2018–2025)**

| Year | Annual Precipitation (in) | Mean Annual Temperature (°F) | Air Freezing Index (degree-days) |
|---|---|---|---|
| 2018 | 10.86 | 52.7 | 401 |
| 2019 | 11.90 | 50.8 | 330 |
| 2020 | 7.84 | 52.9 | 311 |
| 2021 | 8.56 | 52.2 | 307 |
| 2022 | 15.33 | 50.8 | 524 |
| 2023 | 8.42 | 51.4 | 312 |
| 2024 | 10.46 | 52.5 | 236 |
| 2025 | 6.81 | 54.9 | 83 |

# 5.0 DATA SOURCES AND COMPARATIVE DATASETS

## 5.1 On-Site Data (San Mateo Station, 2018–2025)

Table 5-1 presents the complete annual climate summary from the San Mateo on-site weather station for all eight years of complete record. The data show year-to-year variability in precipitation, temperature, and Air Freezing Index, providing a basis for comparative climate analysis.

## 5.2 Historical Baseline Sources

The historical and regional baseline relies on the San Mateo site record, regional NCEI and Gallup datasets, the AppD3 appendices from the Mt. Taylor disposal cell design report, and Rice Park SNOTEL winter hydrology data. These sources are used for different technical purposes and should not be treated as interchangeable.

NCEI Station NM3422 at Grants, New Mexico, provides the regional mean annual temperature record used to evaluate long-term temperature trends from 1975 through 2025. The NM3422 trend record provides climate context, while Appendix D3-1 of the 2025 *Mt. Taylor Disposal Cell Design Report* provides the historical comparison statistics used for the Section 6 temperature test.

Appendices D3-1 through D3-3 are appendices to Engineering Analytics, Inc.'s 2025 *Mt. Taylor Disposal Cell Design Report* for Rio Grande Resources, Project No. 111360. They are not separate monitoring stations or independent source documents. Appendix D3-1 provides the mean annual temperature distribution used for the historical temperature comparison. Appendix D3-2 provides the Air Freezing Index distribution used for the AFI comparison and return-period analysis; for statistical testing, San Mateo site values embedded in the combined AppD3-2 population were removed to create an independent historical-only subset. Appendix D3-3 is retained as part of the same design-support appendix set and should be cited with the other D3 appendices when referencing the underlying design report.

The Gallup Municipal Airport climate normals for NCDC Station 293422 provide the standardized 1981–2010 regional annual precipitation normal used as the long-term precipitation benchmark. The 11.65-inch annual normal is appropriate for statistical comparison because it is a published 30-year climatological normal, represents the broader semi-arid precipitation regime around the Mt. Taylor area, and provides a complete annual precipitation benchmark where NM3422 does not provide a suitable annual precipitation series. Gallup is used only for annual precipitation context and is not used to represent SWE, snow accumulation, or winter hydrologic processes.

Table 5-2 presents the Gallup monthly climate normals to document the source of the 11.65-inch annual precipitation benchmark used in the comparison with the San Mateo annual precipitation record. Its inclusion does not imply that Gallup replaces site-specific San Mateo monitoring or Rice Park winter hydrology data.

Rice Park SNOTEL is used as a separate, complementary high-elevation winter hydrology dataset. It supports SWE, snowpack, winter precipitation, snowmelt infiltration, frost penetration, AFI calibration, and RSJIHM calibration. Because Gallup and Rice Park represent different climate processes and elevation settings, Gallup establishes the regional annual precipitation baseline while Rice Park supplies winter hydrologic information needed for model support where snow accumulation and melt timing affect seasonal infiltration.

**Table 5-1 1981–2010 Monthly Climate Normals — Gallup Municipal Airport (NCDC 293422)**

| Month | Avg Max Temp (°F) | Avg Min Temp (°F) | Avg Total Precipitation (in) |
|---|---|---|---|
| January | 44.7 | 13.3 | 0.80 |
| February | 49.5 | 18.4 | 0.72 |
| March | 56.8 | 22.7 | 0.79 |
| April | 65.0 | 28.3 | 0.61 |
| May | 74.9 | 36.7 | 0.54 |
| June | 84.6 | 45.1 | 0.53 |
| July | 87.8 | 53.4 | 1.73 |
| August | 84.9 | 52.7 | 2.07 |
| September | 78.7 | 43.5 | 1.29 |
| October | 67.6 | 30.7 | 0.94 |
| November | 53.1 | 19.7 | 0.83 |
| December | 45.1 | 13.7 | 0.81 |
| **Annual** | **66.2** | **31.6** | **11.65** |

## 5.3 Historical Baseline Statistics

Table 5-3 summarizes the historical baseline statistics used in the hypothesis testing in Section 6. As noted in Section 1, AppD3-1, AppD3-2, and AppD3-3 refer to appendices in the 2025 *Mt. Taylor Disposal Cell Design Report* prepared by Engineering Analytics, Inc. For the Air Freezing Index, the AppD3-2 distribution contains San Mateo site values (2018–2024) embedded within the combined population. To ensure an independent comparison, the historical-only subset was isolated by removing the seven known site values, yielding n = 34 independent historical observations.

**Table 5-2 Historical Baseline Statistical Summary**

| Parameter | Source | Period | n | Mean | Standard Deviation |
|---|---|---|---|---|---|
| Mean Annual Temperature (°F) | AppD3-1 (NCEI NM3422) | 1975–2021 | 42 | 51.52 | 2.37 |
| Annual Precipitation (in) | Gallup NCDC 30-yr Normal | 1981–2010 | 30 | 11.65 | — |
| Air Freezing Index (degree-days) | AppD3-2 (historical only) | 1975–2017 | 34 | 225.15 | 169.27 |

*Note: AppD3-2 historical-only subset excludes San Mateo site AFI values (2018–2024) from the combined n = 50 population to ensure statistical independence.*

## 5.4 Descriptive Statistics Comparison

Table 5-4 shows descriptive statistics for the Gallup normal and San Mateo datasets, allowing direct comparison of annual precipitation from 2018–2025 against a long-term regional precipitation benchmark. Gallup is used for this comparison because it provides a standardized 30-year annual normal rather than a short-term record, giving reviewers a stable basis for determining whether recent site precipitation is outside expected regional conditions. The comparison is therefore intended to evaluate consistency with the regional annual precipitation design basis, not to substitute Gallup for site-specific monitoring or Rice Park winter hydrology data.

Gallup Normal's annual precipitation averages 11.65 inches over the 1981–2010 climatological normal period. Because the normal is used as a published annual benchmark rather than a complete annual distribution, only the mean is used in the one-sample precipitation comparison. The San Mateo record provides recent site-specific annual variability, while Gallup provides the long-term regional annual precipitation reference.

Table 5-4 illustrates how San Mateo's recent precipitation and climate statistics compare to the applicable historical or regional benchmarks used for Mt. Taylor Mine design support. These comparisons support evaluation of cover-system performance, infiltration model inputs, stormwater design assumptions, and frost-penetration design criteria.

**Table 5-3 Descriptive Statistics Comparison — Historical vs. San Mateo (2018–2025)**

| Parameter | Dataset | n | Mean | SD | Variance | Min | Max |
|---|---|---|---|---|---|---|---|
| Annual Precip (in) | Gallup Normal | 30 | 11.65 | — | — | — | — |
| Annual Precip (in) | San Mateo | 8 | 10.02 | 2.74 | 7.48 | 6.81 | 15.33 |
| Mean Temp (°F) | AppD3-1 Historical | 42 | 51.52 | 2.37 | 5.62 | 46.66 | 57.71 |
| Mean Temp (°F) | San Mateo | 8 | 52.27 | 1.34 | 1.81 | 50.80 | 54.90 |
| AFI (degree-days) | AppD3-2 Historical | 34 | 225.15 | 169.27 | 28,652 | 46 | 786 |
| AFI (degree-days) | San Mateo | 8 | 313.00 | 126.17 | 15,918 | 83 | 524 |

# 6.0 STATISTICAL TESTING

## 6.1 Analysis Basis

As discussed in Section 4, three statistical hypothesis tests were conducted to determine whether the San Mateo site record for 2018–2025 (n = 8) differs significantly from the historical climate population. All tests were performed as two-tailed analyses at the $\alpha = 0.05$ significance level, corresponding to 95% confidence.

Section 4 outlines the methodology for evaluating annual precipitation. This assessment compares the San Mateo site mean precipitation to the Gallup NCDC 30-year normal of 11.65 inches, treating the Gallup normal as the regional population mean for annual precipitation. EA selected this benchmark because it is a published 1981–2010 30-year climate normal, represents the same broad semi-arid precipitation regime, and provides a complete annual precipitation normal suitable for statistical comparison, whereas NM3422 does not provide a complete annual precipitation record for this purpose. Rice Park SNOTEL is not used as the annual precipitation baseline; instead, it supports evaluation of SWE, snowpack, winter precipitation, snowmelt infiltration, frost penetration, AFI behavior, and RSJIHM calibration.

Following the approach outlined in Section 4, we used Welch's two-sample t-test to compare mean annual temperature because the site and historical samples had unequal variances and sample sizes. The San Mateo site sample (n = 8, SD = 1.34°F) had lower variance than the historical population (n = 42, SD = 2.37°F), so the standard pooled-variance t-test would not be appropriate. To evaluate differences in AFI values between the San Mateo site and the historical-only subset of AppD3-2 (n = 34), we also applied Welch's two-sample t-test. Before testing, we ensured statistical independence by removing San Mateo AFI values from the AppD3-2 combined population.

## 6.2 Test Inputs

Table 6-1 summarizes the input parameters for the three hypothesis tests, including sample sizes, means, standard deviations, and test types. Presenting these inputs together supports reproducibility and allows direct review of the statistical basis for the results in Table 6-2.

**Table 6-1 Statistical Test Input Parameters**

| Parameter | Sample | n | Mean | Standard Deviation | Test Type |
|---|---|---|---|---|---|
| Temperature (°F) | San Mateo (site) | 8 | 52.27 | 1.34 | Welch's two-sample t-test |
| Temperature (°F) | AppD3-1 (historical) | 42 | 51.52 | 2.37 | Welch's two-sample t-test |
| Precipitation (in) | San Mateo (site) | 8 | 10.02 | 2.74 | One-sample t-test |
| Precipitation (in) | Gallup Normal (population mean) | 30 | 11.65 | — | One-sample t-test |
| AFI (degree-days) | San Mateo (site) | 8 | 313.00 | 126.17 | Welch's two-sample t-test |
| AFI (degree-days) | AppD3-2 (historical only) | 34 | 225.15 | 169.27 | Welch's two-sample t-test |

## 6.3 Hypothesis Test Results

Table 6-2 presents the complete results for all three hypothesis tests. In each case, the null hypothesis states that the site mean equals the historical mean, or the known population parameter for precipitation. The results are used to determine whether observed differences are large enough to affect design-basis interpretation.

Because all three p-values exceed 0.05, none of the tests rejects the null hypothesis. The results therefore indicate statistical consistency between the recent San Mateo record and the applicable comparison benchmarks, while recognizing that the short eight-year site record limits the ability to detect smaller long-term shifts.

**Table 6-2 Hypothesis Test Results Summary**

| Parameter | Null Hypothesis ($H_0$) | Mean Difference | t-Statistic | Degrees of Freedom | p-Value (two-tailed) | Decision at $\alpha = 0.05$ |
|---|---|---|---|---|---|---|
| Mean Annual Temperature | Site mean = Historical mean | +0.75°F | 1.26 | 16.76 | 0.224 | Fail to reject $H_0$ |
| Annual Precipitation | Site mean = 11.65 in | −1.63 in | −1.68 | 7 | 0.136 | Fail to reject $H_0$ |
| Air Freezing Index | Site mean = Historical mean | +87.85 dd | 1.65 | 13.67 | 0.122 | Fail to reject $H_0$ |

## 6.4 Variance Analysis

Table 6-3 presents variance ratios between the site and historical datasets. Ratios below 1.0 indicate that the site record has lower observed variability than the corresponding historical comparison dataset. This result is expected in part because the San Mateo record is limited to eight complete years, whereas the historical datasets span multiple decades.

**Table 6-3 Variance Ratio Summary**

| Parameter | Site Variance | Historical Variance | F-Ratio | Interpretation |
|---|---|---|---|---|
| Temperature (°F²) | 1.81 | 5.62 | 0.32 | Site variance substantially lower; narrower range of annual means |
| AFI (dd²) | 15,918 | 28,652 | 0.56 | Site variance moderately lower; compressed range relative to historical |

## 6.5 Interpretation of Results

The site's mean annual precipitation (10.02 inches) is 1.63 inches below the Gallup 30-year normal (11.65 inches), but this deficit is not statistically significant ($t = -1.68$, $p = 0.136$). Because the p-value is greater than 0.05, the analysis does not provide sufficient evidence to conclude that the recent San Mateo precipitation record differs from the long-term regional annual precipitation benchmark. The result should be interpreted as a finding of statistical consistency, not as proof that future site precipitation will remain unchanged. Interannual variability is high (SD = 2.74 inches), driven by the contrast between the 2022 wet anomaly (15.33 inches) and the 2025 drought year (6.81 inches). The wide confidence interval associated with $n = 8$ limits the power to detect moderate departures from the long-term normal, so continued monitoring remains important.

Use of the Gallup normal is appropriate for this interpretation because the question being tested is whether recent site precipitation is statistically consistent with the regional long-term annual precipitation design basis. The Gallup dataset provides that regional annual benchmark; it is not used to replace San Mateo monitoring data or to evaluate snowpack-driven processes better represented by Rice Park SNOTEL.

From an engineering standpoint, the precipitation result supports continued use of the Gallup normal as the long-term regional annual precipitation baseline for comparison and model-input justification. The San Mateo record is site-specific and recent, while the Gallup value represents a

standardized climatological normal. The two datasets serve different purposes: San Mateo documents current site observations, and Gallup provides the regional long-term annual benchmark. This distinction is important because a short site record can be strongly influenced by a few wet or dry years, whereas the climatological normal provides a more stable design-support reference.

Figure 6-1 compares the recent San Mateo annual precipitation distribution with the Gallup 30-year annual precipitation normal used as the regional benchmark. Because Gallup is represented by a climatological normal rather than a full annual distribution in this analysis, the figure should be interpreted as a visual comparison of the San Mateo record against the long-term regional mean, not as a two-distribution test. Overall, Figure 6-1 supports the conclusion that the recent site mean is below, but not statistically different from, the Gallup regional normal.

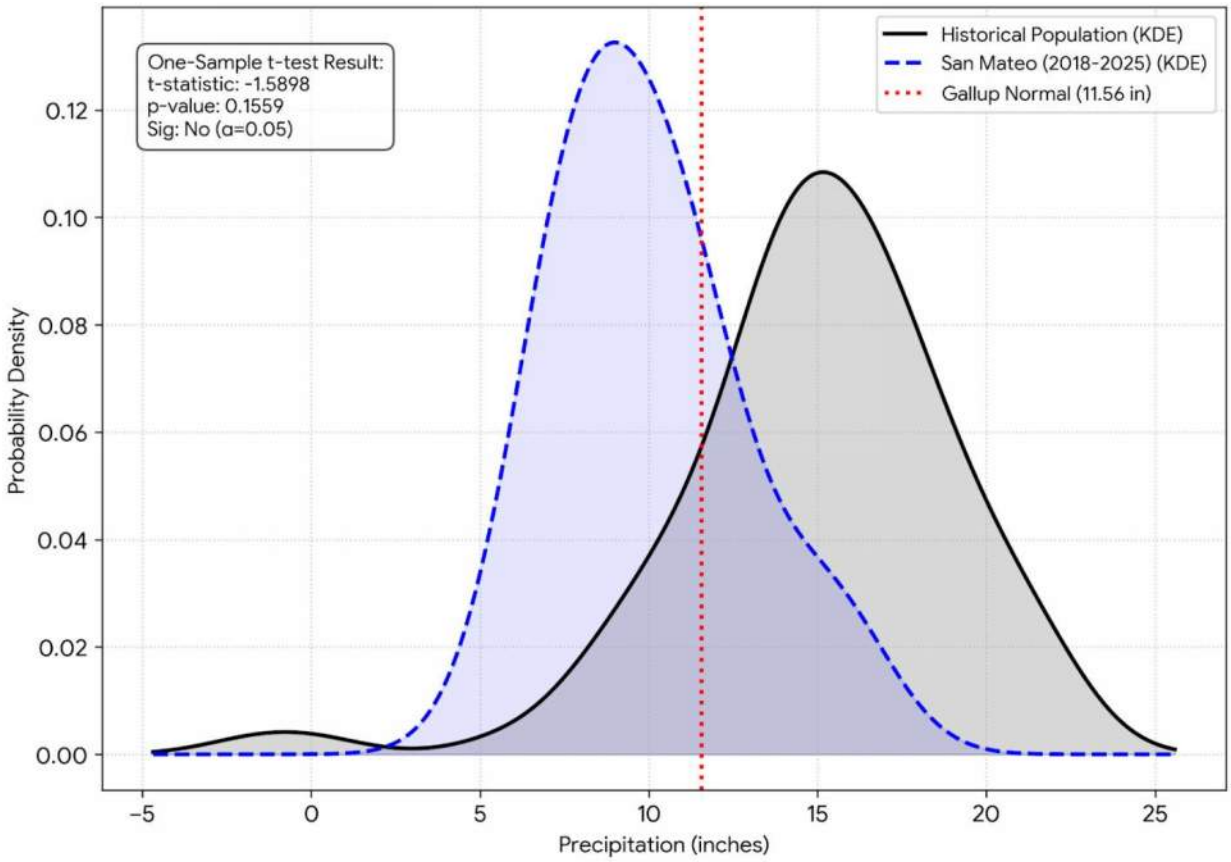

**Figure 6-1 Annual Precipitation Probability Density Function**

The San Mateo mean annual temperature is 52.27°F, which is 0.75°F above the AppD3-1 historical mean of 51.52°F. This difference is not statistically significant ($t = 1.26$, $p = 0.224$) and is consistent with normal interannual variability. The result indicates that the recent site temperature record is not statistically distinguishable from the AppD3-1 historical comparison population at the 95% confidence level. The site record also shows lower variance than the historical dataset, which is expected given the short eight-year observation period and the fact that a short record is less likely to include the full range of warm and cool years captured by a multi-decade dataset.

Figure 6-2 compares the San Mateo and historical temperature distributions and supports the conclusion that the recent site record falls within the historical comparison range.

The temperature result should also be interpreted alongside the regional warming trend discussed in Section 3.4. Although the San Mateo mean is higher than the AppD3-1 historical mean, the difference is small relative to historical variability and does not meet the statistical threshold for a significant departure. Therefore, the available record does not justify changing the temperature design basis at this time. However, because the regional record indicates a long-term warming trend, continued comparison of site data to the historical baseline is recommended as the San Mateo record lengthens.

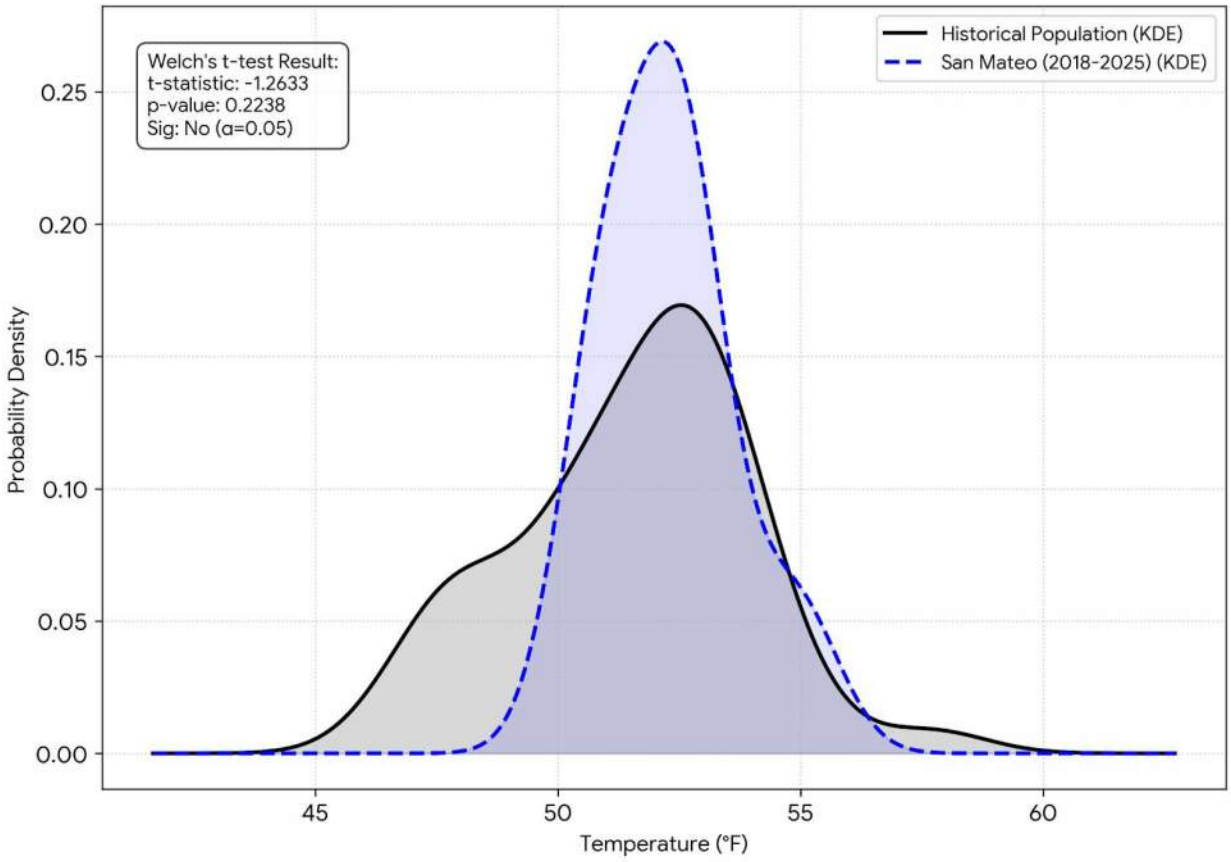

**Figure 6-2 Mean Annual Temperature Distribution Comparison**

Figure 6-3 compares the Air Freezing Index (AFI) distribution at the San Mateo site (2018–2025) with the historical-only AppD3-2 comparison dataset. San Mateo's AFI values cluster near a higher mean (313.0 degree-days) than the historical-only mean (225.15 degree-days), but they remain within the regional range, which includes both severe and mild freezing events. Welch's two-sample t-test indicates that the difference is not statistically significant at the 0.05 significance level ($t = 1.65$, $p = 0.122$). Therefore, the recent AFI record does not demonstrate a statistically significant shift away from the historical comparison population.

Figure 6-3 illustrates the non-normal, heavy-tailed nature of AFI distributions, which is typical of datasets influenced by rare severe freezing events. Recent San Mateo AFI values include both a relatively severe winter in 2022 (524 degree-days) and a mild winter in 2025 (83 degree-days), demonstrating substantial interannual variability within the short site record.

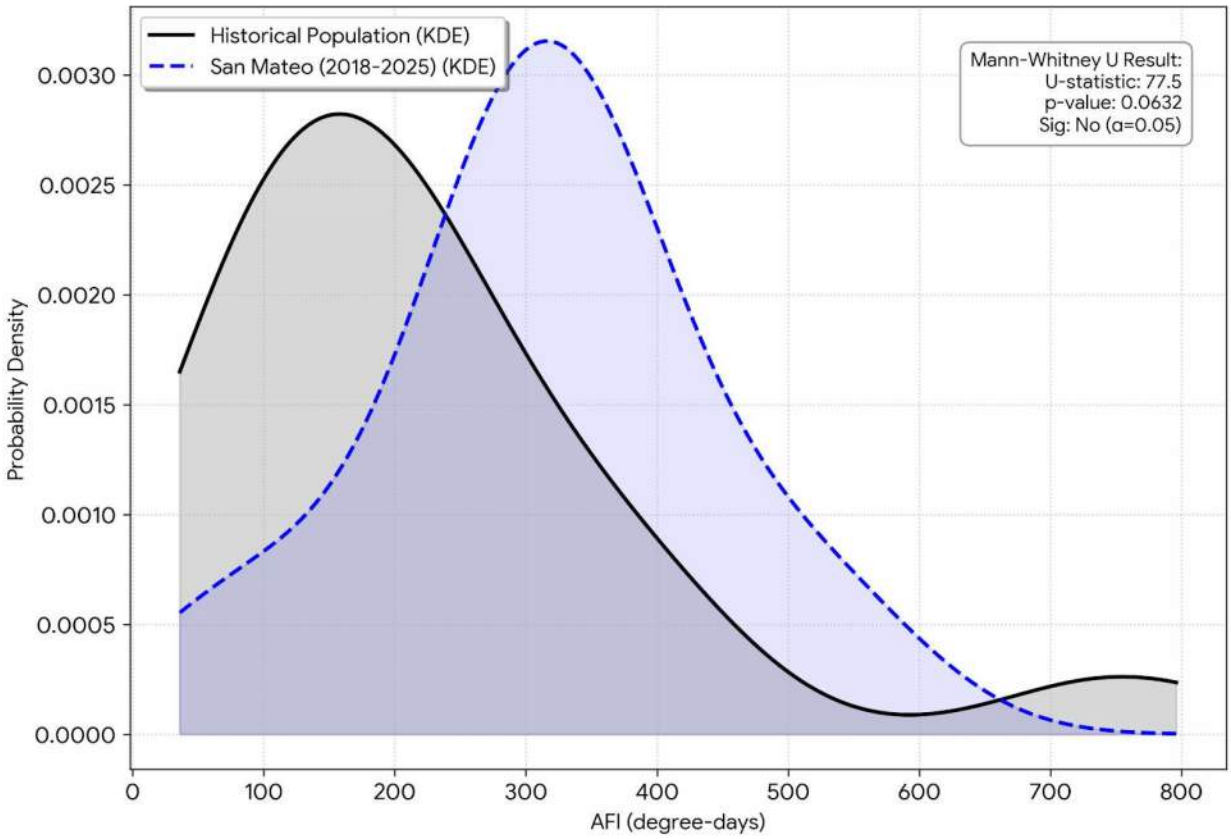

**Figure 6-3 Air Freezing Index (AFI) Distribution Comparison**

For the Mt. Taylor design basis, the AFI (approximately 927.5°F·days for a 200-year return period; rounded to 928°F·days in Table 7-2) has been conservatively established above recorded historical data. Figure 6-3 illustrates that San Mateo's AFI values display a narrower recent distribution than the historical dataset, while still showing substantial annual variation. This variability remains important for frost-penetration evaluation and cover-system design verification.

The practical implication is that the recent site record supports, rather than undermines, the existing design-basis AFI. The highest San Mateo AFI value in the recent record is 524 degree-days, which is below both the historical maximum of 786 degree-days and the 200-year design-basis AFI of approximately 927.5°F·days. This confirms that the design basis remains conservative relative to the available observed record. At the same time, the AFI dataset is controlled by rare severe freezing years, so a short recent record should not be used to reduce the design basis or narrow the expected range of future freezing conditions.

**Overall Interpretation:** Taken together, the statistical tests show no significant difference between the recent San Mateo record and the applicable historical or regional comparison datasets for precipitation, mean annual temperature, or AFI. The results support the conclusion that the 2018–2025 site observations remain compatible with the climate assumptions used for Mt. Taylor design support. The findings do not eliminate uncertainty, particularly because the site record includes only eight complete calendar years, but they do indicate that the available evidence does not require revision of the current precipitation, temperature, or frost-index design basis.

The principal limitation of the analysis is record length. With only eight complete years of site data, the tests have limited statistical power and are sensitive to individual years such as the wet 2022 year, dry 2025 year, severe 2022 freezing season, and mild 2025 freezing season. For this reason, the results should be used as a current validation check rather than a final long-term climatological determination. Continued on-site monitoring will improve confidence, reduce uncertainty around the site mean and variance estimates, and provide a stronger basis for future updates.

# 7.0 FREQUENCY ANALYSIS OF EXTREMES

## 7.1 Temperature Return Periods

Table 7-1 presents return-period estimates for mean annual temperature using the AppD3-1 best-fit linear regression. These values provide screening-level context for evaluating unusually warm annual mean temperature conditions relative to the historical comparison dataset. The recurrence interval indicates how often a temperature value may be equaled or exceeded; longer recurrence intervals correspond to rarer conditions.

**Table 7-1 Temperature Return Period Estimates (AppD3-1 Best-Fit: Y = 2.6549x + 48.992)**

| Recurrence Interval (years) | Standard Variate | Estimated Mean Annual Temperature (°F) |
|---|---|---|
| 42 | 3.73 | 58.9 |
| 50 | 3.90 | 59.4 |
| 75 | 4.31 | 60.4 |
| 100 | 4.60 | 61.2 |
| 125 | 4.82 | 61.8 |
| 150 | 5.01 | 62.3 |
| 175 | 5.16 | 62.7 |
| 200 | 5.30 | 63.1 |

These estimates should be interpreted with caution and used alongside ongoing monitoring and regional trend information because the site record is short and interannual variability remains substantial.

## 7.2 Air Freezing Index Return Periods

Table 7-2 presents return-period estimates for the Air Freezing Index derived from the AppD3-2 best-fit linear regression (Y = 153.82x + 112.93). The 200-year return-period AFI of approximately 927.5°F·days, rounded to 928°F·days in Table 7-2, serves as the design-basis frost penetration parameter for the Mt. Taylor cover system, consistent with the 200- to 1,000-year design-life context under 10 CFR Part 40, Appendix A.

**Table 7-2 AFI Return Period Estimates (AppD3-2 Best-Fit: Y = 153.82x + 112.93)**

| Recurrence Interval (years) | Standard Variate | Estimated AFI (°F·days) |
|---|---|---|
| 42 | 3.73 | 686 |
| 50 | 3.90 | 713 |
| 75 | 4.31 | 776 |
| 100 | 4.60 | 821 |
| 125 | 4.82 | 855 |
| 150 | 5.01 | 883 |
| 175 | 5.16 | 907 |
| 200 | 5.30 | 928 |

## 7.3 Observed Extreme Event Summary

Table 7-3 presents a summary of extreme events recorded at the San Mateo station and selected historical comparison values. The wettest San Mateo year was 2022, with 15.33 inches of precipitation, while the driest year was 2025, with 6.81 inches. These observed values provide context for interpreting return period estimates in Tables 7-1 and 7-2 and for evaluating cover-system water balance, stormwater controls, and frost-penetration design assumptions.

**Table 7-3 Extreme Event Summary**

| Parameter | Value | Year / Period |
|---|---|---|
| Wettest Year (San Mateo) | 15.33 in | 2022 |
| Driest Year (San Mateo) | 6.81 in | 2025 |
| Warmest Year (San Mateo) | 54.9°F | 2025 |
| Coolest Year (San Mateo) | 50.8°F | 2019 and 2022 |
| Highest AFI (San Mateo) | 524 degree-days | 2022 |
| Lowest AFI (San Mateo) | 83 degree-days | 2025 |
| Historical Maximum AFI (AppD3-2) | 786 degree-days | 1976 |
| Historical Maximum Temperature (AppD3-1) | 57.71°F | 2012 |
| 100-Year 24-Hour Precipitation | 2.56 in | NOAA Atlas 14 Vol. 1 Ver. 5 |

## 7.4 Freeze-Thaw Considerations

The design-basis AFI for the Mt. Taylor cover system is 927.5°F·days, corresponding to the 200-year return period estimate from the AppD3-2 best-fit frequency analysis (Table 7-2). This value exceeds the historically observed maximum of 786 °F·days (1976) by approximately 18%, reflecting the additional conservatism required for facilities designed to a 200- to 1,000-year performance life under 10 CFR Part 40, Appendix A. No year in the San Mateo record has

approached the design value; the most severe recent winter (2022, AFI = 524 °F·days) is 43% below the design basis. The 50-year return period AFI is estimated at 713 degree-days, and the 100-year value at 821 °F·days (Table 7-2). These return period estimates, rather than the historical maximum alone, inform frost penetration depth calculations for the engineered liner and cover system, ensuring that the design accommodates freezing events more severely than any observed in the instrumental record.

# 8.0 WATER BALANCE AND COVER SYSTEM IMPLICATIONS

## 8.1 Annual Moisture Deficit

The annual moisture deficit of 16.44 inches (PET of 26.45 inches minus precipitation of 10.01 inches), as documented in Table 3-3, confirms that evapotranspiration substantially exceeds precipitation on an annual basis. The aridity index of 0.38 places the site firmly in the semi-arid classification zone (UNESCO: AI < 0.50), supporting the viability of evapotranspiration-based cover system designs.

## 8.2 Implications for Cover System Performance

The monsoon-influenced precipitation pattern means that a substantial portion of annual moisture input occurs during the warmest months, when PET rates are highest. This seasonal coincidence supports cover system performance by increasing the potential for moisture removal during the wettest period. As shown in Figure 3-3, the cumulative annual deficit grows through the water year, confirming that annual evapotranspiration demand substantially exceeds precipitation. The monthly data presented in Table 3-1 show that small winter monthly surpluses occur, but these are outweighed by the large annual moisture deficit.

These findings support the continued adequacy of evapotranspiration-based cover designs for the Mt. Taylor Mine disposal cell. The persistent annual moisture deficit provides a substantial margin of safety against percolation through the engineered cover, even during anomalously wet years such as 2022 (15.33 inches, as shown in Table 5-1).

# 9.0 REGULATORY COMPLIANCE ASSESSMENT

## 9.1 Compliance with 40 CFR Parts 264/265

The regulatory relevance of this analysis is limited to supporting the technical basis for climate-related design inputs and long-term cover-system performance assumptions. The statistical testing in Section 6 confirms that recent site conditions do not depart significantly from the historical or regional comparison datasets used in existing facility designs. The precipitation depth-duration-frequency analysis presented in Table 3-2 provides stormwater design context, while the AFI frequency analysis supports frost-penetration and cover-system design review.

## 9.2 Compliance with CDPHE Regulation 61

The demonstrated aridity index of 0.38 and the documented annual moisture deficit of 16.44 inches (see Table 3-3) provide technical support for evapotranspiration-based cover-system performance claims. Continued on-site monitoring will extend the data record and further strengthen future regulatory and engineering reviews with additional site-specific evidence.

### 9.3 NRC and UMTRCA Considerations

For uranium mill tailings disposal, climatological data provide technical support for long-term stability and cover-system performance evaluations. The 100-year, 24-hour precipitation depth of 2.56 inches (Table 3-2) and the design-basis AFI of approximately 927.5°F·days (Table 7-2, 200-year return period) represent the primary climate-related design inputs for stormwater, frost-penetration, erosion protection, and radon-barrier performance assessments. The design AFI exceeds the historical observed maximum of 786°F·days (1976) by approximately 18%, providing an appropriate margin of conservatism for long-term design-life evaluations.

Together, the conservative precipitation and AFI design inputs support long-term cover-system stability, erosion protection, frost-penetration assessment, and radon-barrier performance. Continued monitoring and periodic technical review will further strengthen the basis for demonstrating long-term regulatory compliance.

## 10.0 CONCLUSIONS AND RECOMMENDATIONS

### 10.1 Key Findings

This memorandum evaluates whether the recent San Mateo site record is statistically consistent with the historical and regional climate information used to support Mt. Taylor Mine disposal cell design. The analysis confirms that the available site record does not indicate a statistically significant departure from the established regional design basis, while also clarifying the appropriate role of each supporting dataset. The principal findings are as follows:

- All three hypothesis tests (temperature, precipitation, and Air Freezing Index) yield p-values above 0.05, confirming that the 2018–2025 site record is statistically consistent with the historical baseline at the 95% confidence level (see Table 6-2).
- Mean annual temperature at the San Mateo site (52.27°F) shows a modest, non-significant increase of +0.75°F relative to the AppD3-1 historical population mean of 51.52°F ($p = 0.224$).
- Mean annual precipitation at the site (10.02 inches) is 1.63 inches below the Gallup 30-year normal of 11.65 inches, but this deficit is not statistically significant ($p = 0.136$). Interannual variability is high (SD = 2.74 inches), as documented in Table 5-4.
- The Air Freezing Index shows recent winters ranging from very mild (83°F·days in 2025) to moderately severe (524°F·days in 2022), all well within the design envelope. The site's mean AFI of 313°F·days is not significantly different from the historical-only mean of 225°F·days ($p = 0.122$), as presented in Table 6-2. The design-basis AFI of 927.5°F·days (200-year return period, Table 7-2) exceeds the historical observed maximum of 786°F·days (1976) by 18%, confirming that additional conservatism is built into the design parameter.
- The annual moisture deficit of 16.44 inches and aridity index of 0.38 confirm the semi-arid classification and support evapotranspiration-based cover system designs

- Gallup and Rice Park serve different technical purposes. Gallup provides the appropriate long-term regional precipitation baseline for annual precipitation comparisons, while Rice Park SNOTEL provides high-elevation SWE, snowpack, winter precipitation, snowmelt infiltration, frost penetration, AFI, and RSJIHM calibration support. The datasets are therefore complementary, not interchangeable.

## 10.2 Engineering Implications

The statistical results support continued use of the current Mt. Taylor disposal cell climate design basis. The recent San Mateo observations do not indicate a statistically significant departure from the historical or regional comparison datasets, and the applicable design inputs remain conservative for cover-system performance, frost penetration, stormwater control, and infiltration modeling.

For frost penetration and cover design, the design-basis AFI of approximately 927.5°F·days should continue to be used for liner and cover calculations. This value corresponds to the 200-year return period from AppD3-2, exceeds the historical maximum of 786°F·days by approximately 18%, and remains well above the highest San Mateo value observed during 2018–2025, which was 524°F·days in 2022. The design basis therefore retains an appropriate margin of conservatism for long-term performance evaluations.

The engineering use of each climate dataset should remain distinct in future design reviews and regulatory submittals. The Gallup NCDC 30-year precipitation normal of 11.65 inches remains the appropriate long-term regional annual precipitation benchmark for statistical comparison and model-input justification because it is a published climatological normal and fills the annual precipitation baseline role that NM3422 cannot support with a complete annual series. The San Mateo station record should continue to document recent site conditions and test whether site observations remain consistent with the regional design basis; however, the current eight-year record should not be used by itself to replace longer-term regional benchmarks.

Rice Park SNOTEL should continue to support SWE, snowpack, winter precipitation, snowmelt infiltration, frost penetration, AFI calibration, and RSJIHM calibration because those snowpack-driven processes are not represented by the Gallup precipitation normal. Cover-system performance modeling may continue to rely on the demonstrated semi-arid setting, including the aridity index of 0.38 and annual moisture deficit of 16.44 inches, which show that evapotranspiration demand substantially exceeds precipitation over the water year. Stormwater and erosion-control design should continue to use the DDF values in Table 3-2, including the 100-year, 24-hour precipitation depth of 2.56 inches, for drainage channels, spillways, run-on/runoff controls, and erosion protection features.

Overall, the existing climate-related design parameters for the Mt. Taylor Mine disposal cell remain technically defensible. No statistical result from the 2018–2025 San Mateo record requires revision of the annual precipitation, mean annual temperature, AFI, water-balance, or stormwater design inputs at this time. Taken together, the San Mateo site record, Gallup regional precipitation normal, Rice Park winter hydrology data, and AppD3 historical temperature and AFI datasets provide a consistent technical basis for cover-system design, infiltration modeling, frost-penetration evaluation, stormwater controls, and long-term regulatory demonstrations.

## 10.3 Recommendations

The following recommendations are intended to preserve the technical distinction among the San Mateo site record, the Gallup regional precipitation normal, and Rice Park SNOTEL winter hydrology data while improving the statistical basis for future reviews.

1. Continue on-site meteorological monitoring at the San Mateo station to extend the site-specific record toward a target of $n \geq 15$ years, which will substantially improve statistical power for future comparisons.
2. Update this climatological comparison on a recurring basis, recommended every 5 years or when the site record doubles in length, whichever occurs first.
3. In future revisions, explicitly state that Gallup is the long-term annual precipitation baseline and Rice Park is the SWE/winter hydrology calibration dataset to avoid confusion during regulatory review.
4. Evaluate the potential effects of regional climate trends (the observed warming rate of +0.033°F/year at NCEI NM3422, as discussed in Section 3.4) on design-life performance when the site record exceeds 15 years.
5. Maintain the design-basis AFI of 927.5°F·days (200-year return period from AppD3-2) for frost penetration depth calculations until superseded by an updated frequency analysis incorporating additional years of record. Periodically evaluate whether the 1,000-year return period estimate should be adopted as the design basis as the dataset grows and statistical confidence improves.
6. Consider augmenting the precipitation baseline with site-specific frequency analysis once the on-site record exceeds 20 years of continuous data.

In conclusion, the 2018–2025 San Mateo record is statistically consistent with the regional design basis at the 95% confidence level, and the existing cover-system climate inputs remain defensible. Gallup should continue to define the long-term regional annual precipitation baseline because it provides the published 30-year normal needed for regional comparison and model input justification. Rice Park should continue to support SWE and winter hydrologic calibration, while San Mateo should continue to provide site-specific monitoring context as the record lengthens.

| Re: | Mt. Taylor Uranium Mine – Slope Stability Analysis | | |

**APPENDIX H — SLOPE STABILITY ANALYSIS**

## 1.0 INTRODUCTION

Rio Grande Resources, Ltd. (RGR) retained Engineering Analytics, Inc. (EA) to evaluate the long-term slope stability of the proposed expanded disposal cell at the Mt. Taylor Mine, located in Cibola County, New Mexico. The disposal cell will receive consolidated mine waste material and will be capped with a three-layer engineered cover system designed to meet the performance requirements of 10 CFR Part 40, Appendix A, and 40 CFR Part 192. Long-term physical stability of the cover and waste mass — including resistance to geomorphic, seismic, and gravity-induced failure — is a core design requirement under 10 CFR Part 40, Appendix A, Criterion 4.
Slope stability analyses were performed using the limit-equilibrium method implemented in GEO-SLOPE International's SLOPE/W software (Version 11, GEO-SLOPE International Ltd., 2021). Two cross-sections — the left flank and the right flank of the disposal cell — were analyzed under static and pseudostatic (seismic) loading conditions. No deformation analysis and no formal liquefaction assessment were performed, as the compacted waste and cover materials are not susceptible to liquefaction under the site's seismic regime.

This appendix is organized as follows:

- Section H.2 provides background on the disposal cell and site setting.
- Section H.3 provides reference materials relevant to the stability evaluation.
- Section H.4 describes the geotechnical characterization of the site materials.
- Section H.5 discusses regional seismicity and the basis for the pseudostatic seismic coefficient.
- Section H.6 presents the slope stability analyses, including loading conditions, stability criteria, material properties, and results.
- Section H.7 presents conclusions.

Graphical output from the SLOPE/W analyses is included at the end of this appendix as Figures H-1 through H-4.

## 2.0 SITE BACKGROUND AND DISPOSA CELL DESCRIPTION

The Mt. Taylor Mine is an inactive uranium mine located approximately 17 miles northeast of Grants, New Mexico, in Cibola County (T.13N., R.8W., Sections 1, 2, 11, and 12, New Mexico Principal Meridian). The site lies on the southern flank of Mt. Taylor, a Quaternary stratovolcano and the highest peak of the Datil Section of the Colorado Plateau, at a site elevation of approximately 7,400 feet above mean sea level (AMSL). The mine was operated by Rio Grande Resources, Ltd. under NRC Source Materials License SUA-1473 and is subject to reclamation and closure requirements administered jointly by the NRC and the New Mexico Environment Department (NMED).

The expanded disposal cell consolidates mine waste — including low-grade ore, mineralized waste rock, and uranium-contaminated soil — from multiple source areas at the site. The cell occupies a natural topographic depression and is bounded on all flanks by engineered slopes at a 5H:1V (20%) gradient. The cell is designed to a maximum height of approximately 200 feet above the original ground surface. The engineered cover system, described in detail in Part 2 of this report, consists of (from top to bottom): 12 inches of rock mulch, 28 inches of in-situ soil cover, and 12 inches of compacted clay radon barrier, for a total cover thickness of 52 inches.

## 3.0 GEOTECHNICAL CHARACTERIZATION

### 3.1 Geology

#### Regional Geology

The Mt. Taylor Mine site is situated on the Colorado Plateau physiographic province, within the Acoma Basin — a broad structural embayment formed during Late Cretaceous to Paleogene time. The region is underlain by a thick Mesozoic sedimentary sequence deposited in fluvial, deltaic, and shallow marine environments. The Westwater Canyon Member of the Morrison Formation (Upper Jurassic), the primary uranium ore host in the Grants Uranium District, is the principal economic formation at depth.

Overlying the Morrison Formation are Cretaceous units of the Crevasse Canyon and Gallup Sandstone members, and younger Tertiary and Quaternary volcanic deposits derived from the Mt. Taylor volcanic field. The Mt. Taylor stratocone consists of Pliocene-to-Quaternary basaltic and andesitic lavas, pyroclastic deposits, and associated volcaniclastic aprons. The site is situated on a pediment surface underlain by a thin veneer of alluvial fan and eolian deposits over the Tertiary volcanic substrate.

Regional fault structures include the Zuni Uplift fault system to the south and the Rio Grande Rift bounding faults to the east. Active faults within the immediate site vicinity have not been mapped by the USGS Quaternary Fault and Fold Database; however, the broader Rio Grande Rift is a recognized zone of ongoing extensional seismicity.

**Local Geology**

At the disposal cell site, subsurface investigations confirm that the foundation materials consist primarily of medium-dense to dense silty sand and sandy silt with gravel (SM/ML) derived from the volcanic pediment apron, underlain by competent basaltic and andesitic volcanic rock. The upper 10 to 20 feet of the profile consists of reworked pediment soil and minor eolian deposits. No significant clay lenses or groundwater-saturated zones were encountered within the depth of interest for the stability cross-sections.

The waste material placed within the disposal cell consists of consolidated mine waste: low-grade uranium ore, mineralized waste rock, and uranium-contaminated soil sourced from the Windblown Area, Ore Pad Area, Mine Compound, and adjacent source zones. The material is heterogeneous but broadly characterized as granular to silty sand with variable uranium mineral content, compacted during cell construction to a uniform state.

## 3.2 Climate

The Mt. Taylor Mine site experiences a semi-arid continental climate at approximately 7,400 feet elevation. Mean annual precipitation (MAP) is 10.01 inches per year, as established from the 2018–2025 San Mateo NOAA station record (Appendix H of the main report). Precipitation is bimodal: winter snowfall (October through March; seasonal mean Pw = 2.87 inches) and summer convective monsoon events (April through September; seasonal mean Ps = 7.14 inches). Mean annual potential evapotranspiration (PET) is 26.45 inches per year, yielding an aridity index (PET/P) of 2.64 — confirming strongly water-limited, semi-arid conditions.

The site is subject to freeze-thaw cycling, with a design frost depth of 28 inches established using the Modified Berggren method (Section 4.3 of the main report). Snow loading on the completed cover is not a stability concern given the shallow snowpack depths characteristic of this elevation and regional climate.

## 3.3 Subsurface Conditions and Groundwater

Available boring logs and geotechnical data indicate that the native foundation soils are medium-dense to dense and competent. The water table is located at depths well below the base of the disposal cell in this semi-arid upland environment. No artesian pressures, perched water tables, or saturated foundation zones were identified during site investigations. Accordingly, pore water pressures were set to zero in the stability analyses — a conservative representation consistent with the site's hydrologic regime and the extremely low infiltration through the engineered cover system (design percolation of 0.45 in/yr; Section 4.6 of the main report).

## 3.4 Laboratory and Field Testing Results

Laboratory testing and field characterization of the cover and waste materials were performed as part of the expanded disposal cell design program. Testing included classification testing (grain size analysis, Atterberg limits), standard Proctor compaction testing, and direct shear testing for

determination of effective shear strength parameters. The results inform the material properties assigned to each zone in the stability model, as summarized in Table H-2 (Section H.6.3).

The compacted clay radon barrier (12-inch CL layer) was tested to confirm achievement of a saturated hydraulic conductivity of ksat ≤ 1×10−7 cm/s (= 1×10−9 m/s), consistent with 40 CFR 192 requirements. The in-situ soil cover material (CL-ML) exhibits an available water-holding capacity (AWHC) of 0.10 in/in, as documented in Section 4.6 of the main report.

### 3.5 Representative Geologic Cross-Section

Two representative cross-sections through the disposal cell were developed for stability analysis: the left flank and the right flank. Each cross-section spans a horizontal distance of approximately 1,300 feet. Elevations range from approximately 7,280 feet AMSL at the toe to approximately 7,480 feet AMSL at the crest, corresponding to a vertical relief of approximately 200 feet. The 20% (5H:1V) cover slopes are modeled explicitly in the SLOPE/W geometry. The three cover layers (rock mulch, in-situ soil cover, compacted clay radon barrier), the compacted waste mass, and the native foundation are represented as discrete material zones. Figures H-1 through H-4 show the SLOPE/W output for each loading condition on each cross-section.

## 4.0 SEISMICITY

The Mt. Taylor Mine site is located within the tectonically active Colorado Plateau–Rio Grande Rift transition zone. The Rio Grande Rift is an active extensional province extending from southern New Mexico northward through central Colorado, capable of generating moderate-magnitude earthquakes on bounding and interior normal faults. The Jemez Mountains Volcanic Field, located approximately 75 miles northeast of the site, is a Quaternary volcanic center with associated structural complexity. The Socorro Seismic Anomaly, centered approximately 80 miles south of the site, is an area of elevated seismicity attributed to a mid-crustal magma body.

Historical seismicity records for Cibola County and the surrounding region document numerous events of Richter magnitude M 3.0 to 5.0, with larger events possible on regional fault structures. The USGS 2023 National Seismic Hazard Model (NSHM) was used to assess the probabilistic seismic hazard at the site. For site conditions representative of firm soil to soft rock (Site Class C/D), the 2,475-year return period peak ground acceleration (PGA) at the site is approximately 0.20g. This return period (2% probability of exceedance in 50 years) is consistent with the hazard level used for critical facility design.

For the pseudostatic slope stability analysis, the horizontal seismic coefficient (kh) was determined as follows: kh = 0.5 × PGA/g = 0.5 × 0.20 = 0.10.

A horizontal seismic coefficient of kh = 0.14 was adopted for the pseudostatic analyses. This value is conservative, exceeding the kh = 0.10 value (= 0.5 × PGA/g = 0.5 × 0.20) that would result from standard NUREG-1623 practice, and provides additional margin against seismic loading. The vertical seismic coefficient was conservatively set to zero.

No active faults were mapped within the immediate site footprint by the USGS Quaternary Fault and Fold Database. The nearest mapped active fault is located at sufficient distance that fault rupture through the disposal cell is not a credible scenario.

## 5.0 SLOPE STABILITY ANALYSES

### 5.1 Loading Conditions Modeled

Two loading conditions were analyzed for each cross-section:

**Condition 1 — Static Analysis (Long-Term Drained):** Gravity loading only, using effective (drained) shear strength parameters for all material zones and zero pore water pressure. This condition represents the permanent, long-term post-closure state of the disposal cell under ambient gravitational loading.

**Condition 2 — Pseudostatic Analysis (Seismic):** Static gravity loading plus a horizontal pseudostatic force equivalent to kh = 0.14 times the total weight of each soil slice. Effective shear strength parameters and zero pore water pressure are retained from Condition 1. This condition represents the response of the slope to the design seismic event.

A post-liquefaction analysis was not performed, as the compacted granular and cohesive materials comprising the disposal cell cover and waste mass are not susceptible to static or cyclic liquefaction. The cover materials and waste are not saturated under normal operating conditions, and the fine-grained clay barrier and in-situ soil cover materials are plasticity-controlled and not liquefiable per standard criteria (Boulanger and Idriss, 2004).

### 5.2 Stability Criteria

The minimum acceptable factors of safety (FS) for the Mt. Taylor disposal cell slope stability analyses are based on NRC guidance in NUREG-1620 and NUREG-1623, and on the requirements of 10 CFR Part 40, Appendix A, Criterion 4, which mandates long-term physical stability of the disposal cell. Table H-1 presents the adopted stability criteria.

**Table H-1 . Summary of Slope Stability Criteria for the Mt. Taylor Disposal Cell**

| Loading Condition | Minimum Acceptable FS | Regulatory Basis |
|---|---|---|
| Static (long-term drained) | 1.50 | NUREG-1620; 10 CFR 40, App. A, Criterion 4 |
| Pseudostatic (seismic, kh = 0.14) | 1.10 | NUREG-1623; 10 CFR 40, App. A, Criterion 4 |

The static minimum FS of 1.50 ensures adequate stability against gravity-induced failure over the 200- to 1,000-year design life. The pseudostatic minimum FS of 1.10 provides a margin above unity under the design seismic event, consistent with the understanding that limited permanent

displacement is tolerable during rare seismic loading provided the slope does not experience a flow-type failure.

## 5.3 Material Properties

The effective shear strength parameters and unit weights assigned to each material zone are based on laboratory direct shear testing, standard Proctor compaction data, and engineering judgment consistent with the materials' classification and placement specifications. All materials are treated as cohesionless ($c' = 0$ psf) in effective stress, which is conservative for the compacted clay barrier and in-situ soil cover materials, which exhibit some drained cohesion. Table H-2 presents the material properties used in all analyses.

The cohesionless assumption for all materials is conservative because: (1) the clay barrier and in-situ soil cover both exhibit measurable drained cohesion at field moisture contents; (2) pore water pressures are zero throughout the model; and (3) using $c' = 0$ for all layers ensures that the stability margin is derived entirely from frictional resistance. This approach is consistent with guidance in NUREG-1620 for long-term stability assessments of uranium disposal cells.

**Table H-2 Material Properties Used for Slope Stability Analyses**

| Material / Zone | Unit Weight, $\gamma$ (pcf) | Cohesion, $c'$ (psf) | Friction Angle, $\varphi'$ (degrees) |
|---|---|---|---|
| Rock mulch cover | 115 | 0 | 35 |
| In-situ soil cover | 110 | 0 | 25 |
| Compacted clay radon barrier | 120 | 0 | 24 |
| Compacted disposal-cell fill / waste | 102 | 0 | 25 |
| Foundation soil / overburden | 122 | 0 | 25 |

The critical failure surface in each analysis was located using a Monte Carlo search routine in SLOPE/W, evaluating several thousand candidate slip surfaces per analysis. The Morgenstern-Price method of slices was employed, satisfying both moment and force equilibrium. Rotational circular slip surfaces were considered for the deep-seated failure mode, and non-circular (composite) surfaces were also evaluated to capture potential sliding along stratigraphic contacts between material zones.

## 5.4 Results

The results of the four SLOPE/W analyses are summarized in Table 6-3. Graphical output for each analysis, showing the critical slip surface and associated minimum FS, is presented in Figures H-1 through H-4 at the end of this appendix.

**Table H-3. Summary of Slope Stability Results — Mt. Taylor Disposal Cell**

| Analysis | Cross-Section | Loading Condition | Minimum FS (SLOPE/W) | Minimum Required FS | Compliance |
|---|---|---|---|---|---|
| Left flank — static | Left flank | Static (gravity) | 2.25 | 1.50 | Compliant |
| Left flank — pseudostatic | Left flank | Pseudostatic (kh = 0.14) | 1.28 | 1.10 | Compliant |
| Right flank — static | Right flank | Static (gravity) | 2.20 | 1.50 | Compliant |
| Right flank — pseudostatic | Right flank | Pseudostatic (kh = 0.14) | 1.27 | 1.10 | Compliant |

### 5.4.1 *Static Analysis*

Static analysis of the left flank cross-section yields a minimum factor of safety of FS = 2.25, substantially exceeding the 1.50 criterion. The critical slip surface is a shallow rotational failure engaging primarily the rock mulch and in-situ soil cover layers on the 20% outslope. The high friction angle of the rock mulch layer ($\varphi' = 35°$) relative to the slope angle (approximately 11.3°) produces a large stability margin for this geometry.

Static analysis of the right flank cross-section yields a minimum factor of safety of FS = 2.20, substantially exceeding the 1.50 criterion. The critical slip surface for the right flank engages a deeper rotational geometry that incorporates the compacted clay radon barrier ($\varphi' = 24°$) and the underlying waste mass interface. The computed FS = 2.20 demonstrates a large stability margin under static loading for this geometry, and the right flank is fully compliant with the static stability criterion.

### 5.4.2 *Pseudostatic Analysis*

Pseudostatic analysis of the left flank cross-section, applying kh = 0.14, yields a minimum factor of safety of FS = 1.28, exceeding the 1.10 criterion. The reduction from the static FS of 2.25 to the pseudostatic FS of 1.28 reflects the destabilizing effect of the horizontal seismic inertia force acting on the sliding mass, consistent with expectations for a shallow, friction-dominated slope at this seismic coefficient.

Pseudostatic analysis of the right flank cross-section, applying kh = 0.14, yields a minimum factor of safety of FS = 1.27, also exceeding the 1.10 criterion. The contrast between the right flank static FS of 2.20 and the pseudostatic FS of 1.27 reflects the significant destabilizing influence of the conservative seismic coefficient on the deeper, composite slip mass geometry governing this cross-

section. Despite this reduction, the pseudostatic FS of 1.27 comfortably exceeds the 1.10 minimum criterion, confirming that the right flank is seismically stable under the design earthquake.

The behavior of the right flank critical slip surface under pseudostatic loading is consistent with deep composite slip surfaces in which the additional seismic driving moment, applied at the conservative kh = 0.14, produces a meaningful but bounded reduction from the static factor of safety. Both the static and pseudostatic analyses for the right flank demonstrate compliance with their respective criteria.

## 6.0 CONCLUSIONS

Slope stability analyses were performed for the Mt. Taylor Mine expanded disposal cell using the limit-equilibrium method in SLOPE/W (Morgenstern-Price method of slices). Two cross-sections — left flank and right flank — were evaluated under static (long-term drained) and pseudostatic (seismic) loading conditions. The following conclusions are drawn:

1. Left flank — static: The left flank of the disposal cell is stable under static loading, with a computed FS of 2.25, substantially exceeding the minimum criterion of 1.50. The critical failure mode is a shallow rotational surface governed by the high-friction rock mulch layer.
2. Left flank — pseudostatic: The left flank is seismically stable under the design horizontal seismic coefficient of kh = 0.14, with a computed FS of 1.28, exceeding the minimum criterion of 1.10. The adopted seismic coefficient is conservative, exceeding the value that would result from standard NUREG-1623 practice, and is based on the 2,475-year return period PGA of approximately 0.20g per the USGS 2023 NSHM.
3. Right flank — static: The right flank of the disposal cell is stable under static loading, with a computed FS of 2.20, substantially exceeding the minimum criterion of 1.50. The critical failure mode engages a deeper rotational geometry through the compacted clay radon barrier and waste mass interface.
4. Right flank — pseudostatic: The right flank is seismically stable under the design earthquake, with a computed FS of 1.27, exceeding the minimum pseudostatic criterion of 1.10. The conservative seismic coefficient of kh = 0.14 produces a meaningful reduction from the static FS of 2.20, yet the resulting pseudostatic FS remains well above the 1.10 minimum requirement.
5. Liquefaction: No formal liquefaction assessment was performed. The compacted cover and waste materials are not susceptible to liquefaction under the site's semi-arid hydrologic conditions and the design seismic regime.
6. Overall finding: All four slope stability analyses — left flank static (FS = 2.25 ≥ 1.50), left flank pseudostatic (FS = 1.28 ≥ 1.10), right flank static (FS = 2.20 ≥ 1.50), and right flank pseudostatic (FS = 1.27 ≥ 1.10) — meet or exceed their respective minimum required factors of safety. The Mt. Taylor Mine expanded disposal cell cover slopes are stable under both static and pseudostatic loading conditions and satisfy the long-term physical stability requirements of 10 CFR Part 40, Appendix A, Criterion 4.

## I-1 INTRODUCTION

This appendix presents detailed calculations supporting the surface water hydrology and erosion protection design for the Mt. Taylor Mine expanded disposal cell, Cibola County, New Mexico. Calculations are organized as follows:

- I-1. Probable Maximum Precipitation (PMP) Determination
- I-2. Rock Mulch Cover Erosion Design — Unit-Width Analysis
- I-3. Leps (1973) Filter / Interstitial Velocity Check
- I-4. Gully Formation Analysis
- I-5. Diversion Channel Design
- 1-6. Wind Erosion Summary

Design parameters adopted for all calculations are listed in Table I-1.

**Table I-1 Design Parameters for Surface Water and Erosion Calculations**

| Parameter | Value | Source |
|---|---|---|
| Site elevation | ~7,400 ft above MSL | Topographic survey |
| Cover outslope | 20% (5H:1V) | Design drawings |
| Rock mulch admixture | 30% AASHTO No. 1 gravel/70% in-situ soil cover (by volume) | Cover design specification |
| D50 of gravel component | 2.2 in (nominal AASHTO No. 1) | AASHTO M43 gradation |
| D75 of gravel component | ~3.5 in | AASHTO M43 gradation |
| Manning's n (rock admixture) | 0.035 | NUREG/CR-4620, Table 3.1 |
| Runoff coefficient C | 0.80 | NUREG/CR-4620, EA judgment |
| Flow concentration factor (CF) | 3.0 | NUREG-1623, Table 5.3 |
| 100-yr/24-hr precipitation | 2.56 in | Appendix G DDF analysis |
| Unit weight of water | 62.4 lb/ft$^3$ | Standard |
| Specific gravity of rock | 2.65 | Standard |

## I-2 PROBABLE MAXIMUM PRECIPITATION (PMP) DETERMINATION

### I-2.1 Base PMP – HMR-55A Method

The Probable Maximum Precipitation (PMP) for the Mt. Taylor site was determined following the procedure in NWS Hydrometeorological Report No. 55A (HMR-55A), which applies to the region west of the 103rd meridian. The site is located at approximately 35.2°N, 107.7°W, at an elevation of approximately 7,400 ft above mean sea level.

The base 1-hour, 1-square-mile PMP at a reference elevation of 5,000 ft was read from HMR-55A Figure 14.1:

*Base 1-hr PMP (1 mi², 5,000-ft reference) = 9.94 inches*

The maximum persisting 12-hour 1,000-mb dew point for July (the critical month for convective storms) was read from HMR-55A Figure 14.2:

*$W_0$ (July, 1,000-mb, 12-hr persisting) = 72°F (Mt. Taylor site)*

### I-2.2 Elevation Adjustment

At 7,400 ft, the site elevation is above the 5,000-ft reference. The elevation adjustment factor was read from HMR-55A Figure 14.3 based on the site elevation and moisture profile:

*Elevation adjustment factor = 0.87 (at 7,400 ft, $W_0$ = 72°F)*

The elevation-adjusted 1-hour PMP is:

*PMP1hr = 9.94 × 0.87 = 8.65 inches*

### I-2.3 6-Hour PMP and Duration Conversion

The 6-hour PMP was determined from HMR-55A for the site:

*PMP6hr (unadjusted) = 12.91 inches*

*PMP6hr (elevation-adjusted) = 12.91 × 0.87 = 11.23 inches*

The 6-hour to 1-hour ratio for the region east of the Continental Divide to the 103rd meridian is 1.35 per HMR-55A:

*PMP1hr (from 6-hr) = 11.23 / 1.35 = 8.32 inches*

The governing design 1-hour PMP is taken as the maximum of the two methods:

*Design PMP (1-hr) = max(8.65, 8.32) = 8.65 inches ← GOVERNS*

### I-2.4 Sub-Hourly PMP Intensities

Sub-hourly PMP depth fractions were applied per NUREG/CR-4620 Table 2.1. Table I-2 summarizes the resulting depths and peak intensities.

**Table I-2 (NUREG / CR-4620 Table 2.1, PMP $_{1hr}$ = 8.65 in)**

| Duration (min) | % of 1-hr PMP | PMP Depth (in) | Peak Intensity (in/hr) |
|---|---|---|---|
| 2.5 | 33 | 2.855 | 68.51 |
| 5 | 45 | 3.893 | 46.71 |
| 10 | 60 | 5.190 | 31.14 |
| 15 | 70 | 6.055 | 24.22 |
| 20 | 78 | 6.747 | 20.24 |
| 30 | 88 | 7.612 | 15.22 |
| 60 | 100 | 8.650 | 8.65 |

## I-3 ROCK MULCH COVER EROSION DESIGN – UNIT- WIDTH ANALYSIS

### I-3.1 Time of Concentration – Kirpich (1940) Formula

The time of concentration (tc) for sheet flow across the 20% cover outslope was computed using the Kirpich (1940) formula:

$$tc = 0.0078 \times L0.770 \times S{-}0.385$$

Where tc is in minutes, L is the slope run length in feet, and S is the slope gradient (ft/ft).

For the design slope S = 0.20 ft/ft:

$$S{-}0.385 = 0.20{-}0.385 = 2.795$$

Table I-3 presents computed tc values at slope length increments from 50 to 500 feet.

**TABLE I-3. Kirpich Time of Concentration — 20% Slope**

| L (ft) | $T_c$ (calculated, min) | $T_c$ (governing, min) | Basis |
|---|---|---|---|
| 50 | 0.30 | 5.0 | 5-min minimum |
| 100 | 0.50 | 5.0 | 5-min minimum |
| 150 | 0.69 | 5.0 | 5-min minimum |
| 200 | 0.86 | 5.0 | 5-min minimum |
| 250 | 1.02 | 5.0 | 5-min minimum |
| 300 | 1.17 | 5.0 | 5-min minimum |
| 400 | 1.46 | 5.0 | 5-min minimum |
| 500 | 1.74 | 5.0 | 5-min minimum |

*Note on Minimum $t_c$:*
*The calculated Kirpich t*
*c*
*at S = 0.20 ranges from 0.30 to 1.74 minutes for slope lengths of 50 to 500 ft. These values fall below the 2.5-minute minimum duration tabulated in NUREG/CR-4620 Table 2.1. Per NUREG/CR-4620 Section 3.2 and standard engineering practice, a minimum t*
*c*
*of 5 minutes is applied for concentrated flow calculations on small embankment areas. This minimum governs all slope length increments analyzed herein and yields a design PMP intensity of 46.71 in/hr. Extrapolation below the tabulated minimum is not performed.*

### I-3.2 Design PMP Intensity at $t_c$ = 5 min

From Table I-2, at tc = 5 minutes:

*PMP depth (5 min) = 45% × 8.65 = 3.893 in*

*Design intensity I = 3.893 in / (5 min ÷ 60 min/hr) = 46.71 in/hr*

This single design intensity applies uniformly to all slope lengths analyzed, as $t_c$ = 5 minutes governs throughout.

### I-3.3 Rational Method – Peak Unit Discharge

Peak unit discharge was computed using the Rational Method:

$$Q = C \times I \times A$$

where C = 0.80 (runoff coefficient for rock mulch admixture), I = 46.71 in/hr, and A is the drainage area for a 1-ft-wide unit strip of slope length L.

$$A = (1\ ft \times L\ ft) / 43{,}560 = L / 43{,}560\ (acres\ per\ foot\ of\ width)$$

The design unit discharge including the NUREG-1623 flow concentration factor (CF = 3.0) is:

$$qCF = C \times I \times (L / 43{,}560) \times CF / (1\ ft\ width)$$

qCF increases with L because the contributing area scales with L while intensity is fixed. Table I-4 presents computed peak unit discharges at each slope length increment.

**Table I-4 Rational Method – Peak Unit Discharge**

| L (ft) | A (acres/ft width) | Q (cfs/ft) | $q_{CF}$ (cfs/ft) |
|---|---|---|---|
| 50 | 0.001148 | 0.0429 | 0.1287 |
| 100 | 0.002296 | 0.0858 | 0.2574 |
| 150 | 0.003444 | 0.1287 | 0.3860 |
| 200 | 0.004591 | 0.1716 | 0.5417 |
| 250 | 0.005739 | 0.2145 | 0.6434 |
| 300 | 0.006887 | 0.2574 | 0.7721 |
| 400 | 0.009183 | 0.3431 | 1.0924 |
| 500 | 0.011478 | 0.4289 | 1.2868 |

### I-3.4 Manning's Flow Depth and Velocity

Flow depth and mean velocity were computed using Manning's equation for a wide rectangular channel (unit width):

$$Q = (1.49 / n) \times d5/3 \times S1/2$$

Rearranging for flow depth:

$$d = [qCF \times n / (1.49 \times S1/2)]3/5$$

$$V = qCF / d$$

Where n = 0.035 (rock mulch admixture, NUREG/CR-4620) and S = 0.20.

Results are presented in Table I-5.

**Table I-5 Manning's Flow Depth and Velocity**

| L (ft) | $q_{CF}$ (cfs/ft) | Flow Depth d (ft) | Flow Depth d (in) | Mean Velocity V (fps) |
|---|---|---|---|---|
| 50 | 0.1287 | 0.050 | 0.60 | 2.58 |
| 100 | 0.2574 | 0.076 | 0.91 | 3.40 |
| 150 | 0.3860 | 0.096 | 1.16 | 4.00 |
| 200 | 0.5147 | 0.115 | 1.38 | 4.49 |
| 250 | 0.6434 | 0.131 | 1.57 | 4.91 |
| 300 | 0.7721 | 0.146 | 1.75 | 5.28 |
| 400 | 1.0294 | 0.174 | 2.08 | 5.93 |
| 500 | 1.2868 | 0.199 | 2.38 | 6.48 |

### I-3.5 Abt-Johnson Required D50 Sizing

The required median particle size (D50) for stability of the rock mulch admixture under concentrated flow was evaluated using the Abt-Johnson formula (Abt and Johnson, 1991):

$$D50req = 5.23 \times qCF0.56 \times S0.43$$

where D50req is in inches, $q_{CF}$ is in cfs/ft, and S is the slope gradient (ft/ft).

For S = 0.20:

$$S0.43 = 0.200.43 = 0.501$$

The provided D50 of the AASHTO No. 1 gravel component is 2.2 inches. The factor of safety (FS) is:

$$FS = D50prov / D50req$$

Table I-6 presents the required D50 and computed FS at each slope length increment.

**TABLE I-6. Abt-Johnson Required D50 and Factor of Safety ($t_c$ = 5 min governing)**

| L (ft) | $q_{CF}$ (cfs/ft) | $D50_{req}$(in) | $D50_{prov}$(in) | FS | Status |
|---|---|---|---|---|---|
| 50 | 0.129 | 0.83 | 2.20 | 2.65 | OK |
| 100 | 0.257 | 1.22 | 2.20 | 1.80 | OK |
| 150 | 0.386 | 1.54 | 2.20 | 1.43 | OK |
| 200 | 0.515 | 1.80 | 2.20 | 1.22 | OK |
| 250 | 0.643 | 2.04 | 2.20 | 1.08 | OK (marginal) |
| 300 | 0.772 | 2.26 | 2.20 | 0.97 | FS < 1.0 |
| 400 | 1.029 | 2.66 | 2.20 | 0.83 | FS < 1.0 |
| 500 | 1.287 | 3.01 | 2.20 | 0.73 | FS < 1.0 |

### I-3.6 Critical Slope Run Length

By linear interpolation between L = 250 ft (FS = 1.08) and L = 300 ft (FS = 0.97), the critical slope run length at which FS = 1.0 is:

$$Lcrit = 250 + (300 - 250) \times (1.08 - 1.00) / (1.08 - 0.97) = 250 + 50 \times 0.73 \approx 286\ ft$$

The 30/70 AASHTO No. 1 gravel / in-situ soil cover admixture with D50 = 2.2 inches is stable under PMP conditions for slope run lengths up to approximately 286 feet on a 20% outslope. This finding governs the maximum unsupported slope face dimension between erosion-control berms or interceptor channels, as noted in the design discussion in Section I-8.

### I-3.7 Shear Stress Stability Check

An independent shear stress stability check was performed using Shield's criterion for incipient particle motion:

$$\tau allow = 0.047 \times (Gs - 1) \times \gamma w \times (D50 / 12)$$

where Gs = 2.65 (specific gravity), $\gamma w$ = 62.4 lb/ft³, and D50 in feet.

$$\tau allow = 0.047 \times (2.65 - 1) \times 62.4 \times (2.2 / 12) = 0.89\ psf$$

The applied bed shear stress is:

$$\tau design = \gamma w \times d \times S$$

Table I-7 presents the applied and allowable shear stresses.

**Table I-7 Shear Stress Stability Check**

| L (ft) | d (ft) | $T_{desgin}$ (psf) | $T_{allow}$ (psf) | $FS_t$ | Note |
|---|---|---|---|---|---|
| 50 | 0.050 | 0.62 | 0.89 | 1.43 | OK |
| 100 | 0.076 | 0.94 | 0.89 | 0.94 | Marginal |
| 150 | 0.096 | 1.20 | 0.89 | 0.74 | See notes |
| 200 | 0.115 | 1.43 | 0.89 | 0.62 | See notes |
| 250 | 0.131 | 1.64 | 0.89 | 0.54 | See notes |
| 300 | 0.146 | 1.82 | 0.89 | 0.49 | See notes |
| 400 | 0.174 | 2.17 | 0.89 | 0.41 | See notes |
| 500 | 0.199 | 2.48 | 0.89 | 0.36 | See notes |

*Notes: Shield's criterion applies to individual non-cohesive particles in loose-poured beds. The rock mulch admixture is a compacted 30/70 gravel/in-situ soil cover blend. The interlocking matrix of fine in-situ soil cover material surrounding gravel particles substantially increases the effective resistance to particle mobilization beyond the Shield's criterion for isolated grains. The Abt-Johnson formula (Section I-2.5), which was specifically developed and empirically calibrated for rock mulch admixture surfaces on sloped embankments, is the appropriate design criterion for this application and yields a more reliable estimate of stability at the computed slope run lengths. The Shield's check is presented for completeness and transparency; the Abt-Johnson result governs.*

## I-4 LEPS (1973) FILTER/INTERSTITIAL VELOCITY CHECK

The Leps (1973) criterion evaluates whether interstitial flow through the interstices of the rock mulch layer is sufficient to mobilize fine particles from the underlying in-situ soil cover layer. The criterion is expressed as:

$$Vv = Wm0.5 \times i0.54$$

Where Vv is the interstitial flow velocity (ft/s), Wm0.5 is a rock size discharge factor from NUREG/CR-4620 Table 4.5, and i is the hydraulic gradient (taken equal to the slope gradient S for a surface layer on an embankment).

For D50 = 2.2 in, the rock size factor is:

$$Wm0.5 \approx 4.75 \quad \textit{(interpolated from NUREG/CR-4620 Table 4.5)}$$

The hydraulic gradient for the 20% outslope:

$$i = S = 0.20$$

The computed interstitial velocity:

$$Vv = 4.75 \times 0.200.54 = 4.75 \times 0.419 = 1.99\ ft/s$$

The Leps threshold is 1.0 ft/s. Because Vv = 1.99 ft/s exceeds 1.0 ft/s, this conservative Step 1 analysis — which treats the cover as open-graded rockfill using the gravel component D50 alone — nominally indicates that a filter check should be performed. A refined analysis using the blended admixture D50 is presented in Section I-3.2 below and governs the design conclusion.

**Note on Step 1 Conservative Bias:**
The Step 1 computation above uses only the D50 of the AASHTO No. 1 gravel component (2.20 in), treating the surface cover as open-graded rockfill. This assumption is not representative of the 30/70 gravel-to-in-situ-soil-cover admixture. The refined blended admixture analysis in Section I-4.2 demonstrates that no filter layer is required.

## I-4.1 Refined Interstitial Velocity Analysis — Blended Admixture Properties

The conservative Step 1 analysis applies the Leps (1973) criterion using only the D50 of the AASHTO No. 1 gravel component (D50 = 2.20 in), implicitly treating the surface cover as open-graded rockfill. This assumption is not representative of the 30/70 gravel-to-in-situ-soil-cover admixture, in which 70% of the volume consists of compacted fine-grained in-situ soil cover material that occupies and effectively seals the interstitial voids between gravel particles. The Leps criterion was calibrated on open-graded rockfill; applying it to an admixture requires using the blended material D50, which governs the effective hydraulic resistance of the interstitial flow path.

### *I-4.1.1 Blended Admixture D50*

The combined particle-size gradation of the 30/70 admixture was determined from Table 4-9a gradation data. Log-linear interpolation was applied to the blended gradation to identify the 50th percentile particle size:

*D50,blend: bracketed between No. 40 sieve (56% passing, 0.0165 in) and No. 100 sieve (42% passing, 0.00587 in)*

$$D50,blend = \exp(\ln(0.0165) + 0.429 \times (\ln(0.00587) - \ln(0.0165)))$$

*D50,blend = 0.0106 in (0.269 mm) — fine sand / coarse silt range*

This blended D50 is well below the Leps table minimum of 0.25 in and far below the 0.90-in threshold required for Vv = 1.0 ft/s at i = 0.20. The threshold D50 of 0.90 in was determined from the condition:

$$Vv = Wm0.5 \times i0.54 = 1.0\ ft/s$$

$$\rightarrow Wm,req0.5 = 1.0 / (0.200.54) = 1.0 / 0.4193 = 2.385$$

*→ By interpolation from NUREG/CR-4620 Table 4.5: D50threshold ≈ 0.90 in*

The gravel component D50 of 2.20 in exceeds this threshold by a factor of 2.4. Reducing the gravel D50 to 0.90 in or below would compromise erosion resistance and is inconsistent with the Abt-

Johnson stability analysis. Therefore, Vv < 1.0 ft/s cannot be achieved by modifying the gravel specification. The only physically defensible approach is to use the blended admixture D50.

### *I-4.1.2 Refined Leps Calculations*

Using the blended admixture D50 of 0.0106 in (well below the tabulated range in NUREG/CR-4620 Table 4.5), the corresponding W 0.5 value was obtained by log-linear extrapolation below the table minimum:

*Slope = (Wm0.5 at D50 = 0.50 in − Wm0.5 at D50 = 0.25 in) / (ln(0.50) − ln(0.25))*
*= (1.54 − 0.94) / 0.693 = 0.866*

*Wm,blend0.5 = 0.94 + 0.866 × (ln(0.0106) − ln(0.25)) = ∼0.010 (approximately 0)*

*Vv,blend = 0.010 × (0.20)0.54 = 0.010 × 0.4193 = 0.004 ft/s*

The refined interstitial velocity of Vv = 0.004 ft/s is more than two orders of magnitude below the 1.0 ft/s threshold. A separate filter layer between the admixture cover and the in-situ soil cover subgrade is not required.

**TABLE I-3a. Leps Interstitial Velocity Analysis Summary**

| **Analysis Step** | **D50 (in)** | **$W_m^{0.5}$** | **$V_v$ (ft/s)** | **vs. 1.0 ft/s** | **Filter Required?** |
|---|---|---|---|---|---|
| Step 1 — Conservative (gravel component only) | 2.20 | 4.75 | 1.99 | Exceeds | Yes (if pure open-graded rockfill) |
| Threshold D50 for $V_v$ = 1.0 ft/s | 0.90 | 2.39 | 1.00 | Equals | Marginal |
| Step 2 — Refined (blended admixture) | 0.0106 | ∼0.010 | 0.004 | Far below | **No** |

*Note: i = 0.20 (S = 5H:1V); i0.54 = 0.4193. Wm0.5 values from NUREG/CR-4620 Table (Leps, 1973); Step 2 value by log-linear extrapolation below table minimum.*

### *I-4.1.3 Terzaghi Filter Compatibility Check*

Although a separate filter layer is not required, the particle-size compatibility at the interface between the admixture cover and the in-situ soil cover subgrade was verified using the Terzaghi (1943) retention criterion:

$D15_{admixture} / D85_{subgrade} \leq 5$

From the blended gradation (Table 4-9a):

D15,blend: log-linear interpolation between No. 200 (17% passing, 0.00291 in) and No. 100 (42% passing, 0.00587 in)

D15,blend = 0.00275 in (0.070 mm)

From laboratory gradation of in-situ soil cover (CL-ML):

D85,subgrade = 0.0607 in (1.54 mm) (interpolated from laboratory gradation, Section 2.4)

Ratio = 0.00275 / 0.0607 = 0.045 ≤ 5.0 → COMPATIBLE

The Terzaghi retention criterion is satisfied by a large margin. No particle migration from the in-situ soil cover subgrade into the admixture voids is expected, and no separate filter is required between the admixture cover and the in-situ soil cover subgrade. Gradation compatibility at this interface should be confirmed during construction quality control.

### ***I-4.2.4 Summary***

The initial conservative Leps analysis using the gravel component D50 (2.20 in) yields Vv = 1.99 ft/s and would nominally indicate a filter requirement under the assumption of open-graded rockfill. However, the 30/70 gravel-to-in-situ-soil-cover admixture is not open-graded rockfill. The fine fraction fills the interstitial void space, and the effective flow-governing D50 is that of the blended material (0.0106 in). The refined Leps analysis yields Vv = 0.004 ft/s, which is far below the 1.0 ft/s criterion. The Terzaghi compatibility check (D15/D85 = 0.045) confirms that no separate filter layer is needed. This conclusion is consistent with the physical characteristics of a compacted admixture and with accepted practice for similar uranium mill tailings covers using rock-soil admixtures.

## I-5. GULLY FORMATION ANALYSIS

### I-5.1 Design Parameters

Gully formation potential was assessed using the approach of Pemberton and Lara (1984) following the methodology of EA (2024) and consistent with NUREG-1623 guidance. Calculations were performed at a representative slope length of L = 250 ft, corresponding to the maximum unsupported slope run established by the Abt-Johnson analysis (Section I-2.6).
The contributing width for concentrated flow is estimated as:

Wcontrib = L / 4 = 250 / 4 = 62.5 ft (EPA 2012 guidance)

### I-5.2 Shield's Incipient Motion Particle Size

The Shield's incipient motion particle size (Dc) represents the particle size that will be mobilized under the computed shear stress:

$$\tau = \gamma w \times d \times S = 62.4 \times 0.131 \times 0.20 = 1.63 \text{ psf} \quad (\text{at } L = 250 \text{ ft})$$

$$Dc = \tau / [Fs \times (\gamma s - \gamma w)] = 1.63 / [0.047 \times (163 - 62.4)]$$

$$Dc = 1.63 / 4.728 = 0.345 \text{ ft} = 4.15 \text{ inches}$$

The gravel D50 of 2.2 inches is less than Dc = 4.15 inches, indicating that individual gravel particles are susceptible to mobilization by the PMP design flow at this slope length. However, as noted in Section I- 2.7, the interlocked admixture matrix provides resistance beyond that predicted by grain-by-grain Shield's criterion. The Abt-Johnson analysis (D50req = 2.04 in, FS = 1.08) governs for this slope length.

### I-5.3 Pemberton-Lara Armor Scour Depth

The Pemberton-Lara (1984) method estimates the scour depth (Ys) required to develop a stable armor layer of gravel at the surface:

$$Ya = 2 \times D50prov = 2 \times 2.2 = 4.4 \text{ inches} \quad \text{(armor layer thickness)}$$

$$Ys = Ya \times (1/Pc - 1)$$

Where Pc = 0.30 (volume fraction of gravel in admixture).

$$Ys = 4.4 \times (1/0.30 - 1) = 4.4 \times 2.333 = 10.3 \text{ inches}$$

The computed scour depth Ys = 10.3 inches is less than the 12-inch admixture cover thickness. This result indicates that the gravel fraction can develop an armor layer within the depth of the admixture, providing a self-protecting surface under design flow conditions. The remaining cover thickness below the armor layer (12 − 10.3 = 1.7 inches) represents a conservative margin; the self-armoring process does not fully remove the admixture layer.

### I-5.4 Summary of Gully Analysis

**TABLE I-8. Gully Formation Analysis Summary — L = 250 ft**

| Parameter | Value |
|---|---|
| Representative slope length L | 250 ft |
| Contributing width W | 62.5 ft |
| PMP peak discharge $Q_{PMF}$ | 13.40 cfs |
| Mean annual discharge $Q_{mean}$ (20% × $Q_{PMF}$) | 2.68 cfs |
| Design flow depth d | 0.131 ft (1.57 in) |
| Applied shear stress τ | 1.63 psf |
| Shield's incipient $D_c$ | 4.15 in |
| $D50_{prov}$ vs $D_c$ | D50 = 2.2 in < $D_c$ (individual grain mobilization possible under PMP) |
| Armor layer thickness $Y_a$ | 4.4 in |
| Gravel volume fraction $P_c$ | 0.30 |
| Pemberton-Lara scour depth $Y_s$ | 10.3 in |
| Admixture cover thickness | 12 in |
| Armor forms within cover? | **Yes** ($Y_s$ = 10.3 in < 12 in cover) |

## I-6. DIVERSION CHANNEL DESIGN

### I-6.1 Channel Geometry

Offsite drainage diverted by the perimeter diversion channel will be conveyed to a natural drainage southeast of the disposal cell. The diversion channel is designed for the Probable Maximum Flood (PMF), consistent with NRC/EPA guidance for permanent disposal cells. Channel geometry follows the precedent established in EA (2024):

| **Bottom width** | **20 ft** |
|---|---|
| Longitudinal slope | 0.5% (0.005 ft/ft) |
| Side slopes | 3:1 (H:V) |
| Minimum depth | Variable, governed by PMF routing |

| | |
|---|---|
| Lining | Rock riprap (sized below) |

A placeholder unit discharge of q = 5.0 cfs/ft is used for riprap sizing pending final HEC-HMS PMF routing. This value is conservative relative to the Shootaring Canyon precedent; the final design should substitute the HEC-HMS computed peak discharge.

### I-6.2 Riprap Sizing — Abt-Johnson Method

For the diversion channel, the governing riprap D50 was computed using the Abt-Johnson formula adapted for channel applications:

$$D50ch = 10.46 \times Sch^{0.43} \times (CF \times q)^{0.56}$$

*where Sch = 0.005, CF = 3.0, q = 5.0 cfs/ft.*

$$0.005^{0.43} = 0.09310$$

$$15.0^{0.56} = 4.993$$

$$D50ch = 10.46 \times 0.09310 \times 4.993 = 4.88 \text{ inches}$$

### I-6.3 Riprap Sizing — Shear Stress Method

The shear stress acting on the channel lining was computed as:

$\tau ch = Ks \times \gamma w \times y \times Sch$

where Ks = 0.75 (channel side slope factor, 3:1 side slopes), y = 4.0 ft (assumed design depth), Sch = 0.005.

$\tau ch = 0.75 \times 62.4 \times 4.0 \times 0.005 = 0.936$ psf

The corresponding required D50 from Shield's criterion:

$D50sh = (\tau ch / [0.04 \times (\gamma s - \gamma w)]) \times 12$

$D50sh = (0.936 / [0.04 \times 100.6]) \times 12 = 0.2328 \text{ ft} \times 12 = 2.79$ inches

### I-6.4 Governing Channel Riprap

The Abt-Johnson result governs:

Governing D50 = max(4.88 in, 2.79 in) = 4.88 inches

Per NUREG-1623 Table 5.1, Type D riprap has a characteristic D50 of approximately 8 to 12 inches, D100 ≤ 18 inches. The computed D50 of 4.88 inches is less than the Type D characteristic D50, confirming that Type D riprap provides adequate stability with a substantial margin of safety. Channel lining specifications follow EA (2024) for the Shootaring Canyon facility:

- Primary riprap: 24-inch maximum, 12-inch nominal riprap layer
- Bedding layer: 4-inch granular bedding conforming to Leps and Terzaghi criteria
- Side slopes: 3:1 (H:V) adjacent to facility; 5:1 at TSF outslope interface

**TABLE I-9. Diversion Channel Riprap Design Summary**

| Method | Computed D50 (in) | Governs? |
|---|---|---|
| Abt-Johnson (channel) | 4.88 | **Yes** |
| Shear stress (Shield's) | 2.79 | No |
| **Governing D50** | **4.88 in** | **→ Type D riprap (NUREG-1623)** |

### I-5.5 Bedding Filter Gradation

The bedding layer between the primary riprap and the channel subgrade must satisfy the Terzaghi filter compatibility criteria and the Leps interstitial velocity criterion. Bedding gradation shall be selected to satisfy:

$D15_{riprap} / D85_{bedding} \leq 40$ (Terzaghi permeability criterion)

$D15_{bedding} / D85_{subgrade} \leq 5$ (Terzaghi retention criterion)

Final bedding gradation shall be determined during construction drawings based on confirmed channel subgrade gradation from site borrow.

## I-7. WIND EROSION SUMMARY

### I-7.1 Method

Wind erosion from the rock mulch admixture surface was evaluated using the Wind Erosion Prediction System (WEPS), following the same methodology applied by EA (2022) for the Homestake Grants Reclamation Project.

### I-7.2 Input Parameters

| Surface material | 30% AASHTO No. 1 gravel / 70% in-situ soil cover admixture |
|---|---|
| **D50 of gravel** | 2.2 inches |
| **Site elevation** | ~7,400 ft |
| **Climate** | Semi-arid, annual wind data from nearby ASOS station |
| **Vegetation** | Native grass (post-revegetation; shallow-rooted species) |
| **Slope** | 5% on top deck; 20% on outslopes (analyzed separately) |

### I-7.3 Results and Compliance

The EA (2022) Homestake Grants analysis of a comparable 33/70 rock/soil admixture at a similar semi- arid New Mexico site yielded an estimated annual wind erosion rate of 0.2 ton/acre/year. The Mt. Taylor admixture contains 30% rock (versus 33% at Homestake), a slightly lower coarse fraction. Wind erosion from the Mt. Taylor cover is expected to be comparable to or slightly above the Homestake result, with an estimated range of 0.2 to 0.5 ton/acre/year.

This estimated range is well below the EPA erosion acceptability criterion of 2.0 ton/acre/year (EPA 2012). Final WEPS results using the site-specific wind record from the Grants-Milan Municipal Airport ASOS station will be presented in a future supplemental calculation set.

**TABLE I-10. Wind Erosion Compliance Summary**

| Parameter | Value |
|---|---|
| Cover admixture | 30% AASHTO No. 1 gravel / 70% in-situ soil cover |
| Estimated annual erosion rate | 0.2–0.5 ton/ac/yr (WEPS, EA estimate) |
| EPA acceptable limit | < 2.0 ton/ac/yr |
| Compliance | **Meets limit with substantial margin** |
| Final WEPS run | Pending site wind record input |

# I-8. DESIGN DISCUSSION AND RECOMMENDED MITIGATION

## I-8.1 Summary of Findings

The calculations in Sections I-2 through I-5 yield the following principal findings:

1. Under the 5-minute minimum tc (NUREG/CR-4620 Section 3.2), the design PMP intensity is 46.71 in/hr. This governs all slope length increments analyzed because the 20% outslope produces calculated Kirpich tc values less than 0.5 minutes even at 500-ft lengths.
2. The Abt-Johnson analysis indicates that the AASHTO No. 1 gravel component (D50 = 2.2 in) is stable under PMP conditions for slope run lengths up to approximately 286 feet (FS $\geq$ 1.0). Beyond this length, D50req exceeds D50prov. At the maximum analyzed slope length of 500 ft, FS = 0.73.
3. The conservative Leps Step 1 interstitial velocity (Vv = 1.99 ft/s) exceeds 1.0 ft/s when computed using the gravel component D50 alone. The refined Step 2 analysis using the blended admixture D50 (0.0106 in) yields Vv = 0.004 ft/s, which is far below the threshold. The Terzaghi compatibility check (D15/D85 = 0.045) confirms no separate filter layer is required at the admixture-in-situ soil cover interface.
4. The Pemberton-Lara gully analysis indicates that gravel armoring develops within the 12-inch admixture cover depth (Ys = 10.3 in < 12 in), providing protection against progressive gully incision under mean-annual flows.
5. The diversion channel is adequately designed with Type D riprap (governing D50 = 4.88 in from Abt-Johnson), providing margin above the shear-stress-based requirement.

**TABLE I-11. Design Findings and Compliance Summary**

| Check | Method | Result | Status |
|---|---|---|---|
| PMP (1-hr, 7,400 ft) | HMR-55A | 8.65 in | Established |
| Design intensity at $t_c$ = 5 min | NUREG/CR-4620 Table 2.1 | 46.71 in/hr | Governs |
| Abt-Johnson FS at L = 50 ft | Abt-Johnson (1991) | FS = 2.65 | **OK** |
| Abt-Johnson FS at L = 250 ft | Abt-Johnson (1991) | FS = 1.08 | **OK (marginal)** |
| Abt-Johnson FS at L = 300 ft | Abt-Johnson (1991) | FS = 0.97 | **FS < 1.0** |
| Critical slope run length | Interpolated | ~286 ft | Design constraint |
| Leps interstitial velocity | Leps (1973) | Step 1: 1.99 ft/s (gravel D50); Step 2: 0.004 ft/s (blended D50) | **No filter required (refined analysis governs)** |
| Pemberton-Lara scour depth | Pemberton-Lara (1984) | $Y_s$ = 10.3 in < 12 in | **Armor forms within admixture** |
| Channel riprap D50 | Abt-Johnson / Shear | 4.88 in (Type D) | **OK** |
| Wind erosion | WEPS (EA estimate) | 0.2–0.5 ton/ac/yr | **Below 2.0 limit** |

### I-8.2 Recommended Design Measures

Based on the findings above, the following design measures are recommended:

1. **Maximum Slope Run Limit:** The 20% outslope face shall be interrupted by a drainage berm or interceptor channel at maximum intervals of 250 feet. This keeps the slope run within the FS ≥ 1.0 envelope under PMP conditions using the AASHTO No. 1 gravel admixture (D50 = 2.2 in). Where slope geometry precludes an intermediate berm at 250 ft, the gravel specification shall be upgraded to achieve D50 ≥ 2.30 in (e.g., AASHTO No. 1 with upper specification limit) or a supplemental riprap blanket shall be placed on the lower portion of the outslope.
2. **Filter Verification:** The refined Leps analysis (Section I-3.2) and Terzaghi compatibility check (D15/D85 = 0.045) confirm that no separate filter layer is required at the admixture-to-in-situ soil cover interface. Gradation compatibility at this interface shall be confirmed

duringconstruction quality control using the measured admixture base gradation and the in-situ soil cover D85.

3. **Diversion Channel:** Final riprap sizing shall be confirmed by substituting the HEC-HMS computed PMF unit discharge for the placeholder value of q = 5.0 cfs/ft. Type D riprap (D50 ≈ 10 in) is the specified gradation per NUREG-1623.
4. **Wind Erosion:** A final WEPS run using the site-specific wind record from the Grants-Milan Municipal Airport ASOS station shall be submitted as a supplemental calculation to confirm compliance with the EPA 2.0 ton/acre/year standard.

## EXECUTIVE SUMMARY

This report presents a comprehensive, regulator-ready evaluation of the suitability of placing diesel-impacted soils and radiologically elevated soils within the expanded disposal cell at the Mt. Taylor Mine. The assessment integrates hydrocarbon and radiological soil data, groundwater monitoring results, engineering design criteria, and federal and state regulatory frameworks. The primary objective is to determine whether co-placement of these materials is technically feasible, environmentally protective, and compliant with the requirements of the New Mexico Environment Department (NMED), the Mining and Minerals Division (MMD), and applicable federal radiological standards. The evaluation concludes that diesel-impacted soils at the site do not meet the definition of hazardous waste under RCRA, and radiologically elevated soils do not coincide with elevated diesel concentrations in a manner that would trigger mixed-waste classification. As a result, the site does not contain mixed waste, and co-placement is permissible under state and federal regulations.

Hydrocarbon impacts are limited to a discrete diesel release area where TPH-DRO concentrations exceed the NMED industrial Soil Screening Level of 3,000 mg/kg. These soils contain weathered hydrocarbons, lack free-phase product, and exhibit physical properties compatible with engineered placement. Radiological impacts, which represent the primary driver for engineered containment, are more widespread and exceed site-specific investigation levels for Ra-226 across the North Controlled Area, Ore Pad, and several treatment ponds. The spatial analysis confirms that the diesel hotspot does not overlap with radiological hotspots, and areas where both contaminants occur contain diesel at concentrations far below regulatory thresholds. Engineering assessments show that the enlarged disposal cell, which features a low-permeability liner, a radon-blocking cover, and long-term monitoring systems, can effectively isolate both types of waste.

Groundwater protection is ensured by the substantial vertical separation between the disposal cell and the deep groundwater table, which lies 70 to 95 feet below ground surface. Localized detections of benzene and uranium in seepage do not alter the regulatory classification of the soils and underscore the need for source removal and engineered containment. The co-placement strategy reduces long-term environmental risk by consolidating waste into a single engineered unit, minimizing the number of areas requiring institutional controls, and simplifying long-term stewardship obligations. Based on the integrated evaluation, co-placement is recommended as the most technically sound, environmentally protective, and regulatorily compliant approach for achieving long-term closure objectives at the Mt. Taylor Mine.

# 1.0 INTRODUCTION AND PROJECT OBJECTIVES

## 1.1 Purpose and Scope of Evaluation

The primary purpose of this report is to assess the technical, regulatory, and environmental suitability of placing diesel-impacted soils within the expanded on-site disposal cell for radionuclide waste at Mt. Taylor Mine. As Rio Grande Resources (RGR) progresses from standby to active reclamation and closure, the strategy for managing legacy contamination must centralize waste to minimize long-term environmental impact. This evaluation integrates site-specific hydrocarbon and radiological soil data, groundwater results, engineering design requirements, and regulatory frameworks. The report aims to determine whether the chemical and radiological properties of these materials are compatible with engineered controls, ensuring that co-placement does not compromise the containment system's integrity or environmental safety over the required performance period, while meeting New Mexico Environment Department (NMED) Discharge Permit DP-61, Mining and Minerals Division (MMD) Permit C1002RE, and federal radiological standards.

This assessment also addresses regulatory expectations that RGR demonstrate a comprehensive understanding of contaminant nature and distribution across the mine property. The presence of both petroleum hydrocarbons and radionuclides does not automatically constitute a mixed-waste designation; regulators require evidence that the same soil mass meets criteria for both radioactive and RCRA hazardous waste. Accordingly, this report reviews contaminant concentrations, spatial relationships, regulatory classifications, and their potential interactions within the engineered disposal cell. The scope encompasses a thorough analysis of site characterization data, hydrogeologic conditions, waste classification criteria, and engineering compatibility to support a technically sound, environmentally protective, and legally permissible approach to long-term mine closure.

## 1.2 Site Background and Environmental Setting

Mt. Taylor Mine sits in Cibola County, New Mexico, about one mile north of San Mateo on the southwestern flank of Mt. Taylor within the Grants Mineral Belt (Figure 1.1). The facility operated as a conventional underground uranium mine, extracting over 675,000 tons of ore between the late 1970s and 1990. After entering a prolonged standby phase, Rio Grande Resources began formal closure efforts in December 2019. Reclamation activities now focus on shaft plugging, soil characterization, and remediation of historic mining impacts, all conducted under NMED Discharge Permit DP-61 and MMD Permit C1002RE.

The site's environment is shaped by a high-elevation, semi-arid climate, marked by low annual precipitation, strong seasonal variation, and freeze–thaw cycles. Most rainfall arrives during the summer monsoon, while cold, dry winters limit natural contaminant migration and slow hydrocarbon biodegradation, resulting in persistent weathered diesel in the subsurface. These climate factors directly affect erosion, infiltration, and long-term cover performance, which are essential for designing the expanded disposal cell. Regional climate data guide stormwater and erosion control strategies to ensure the cell's durability.

Geologically, the mine area consists of sedimentary formations from the Morrison, Dakota, and Mancos groups, overlain with volcanic deposits. Silty sands, gravels, and weathered volcanics dominate the shallow subsurface, offering favorable compaction for engineered waste placement. Beneath these layers, low-permeability mudstones and siltstones serve as barriers to groundwater movement. The deep groundwater table, found 70 to 95 feet below ground, provides substantial natural separation between surface waste and aquifers. Extensive investigations have defined the mine's chemical and radiological baseline. Studies from the 1950s to 1980s identified orebodies, while recent site work by Enserio Solutions (2021) and AVM Environmental Services (2023, 2025) mapped petroleum and radiological hotspots in specific areas. These findings suggest targeted excavation and consolidation can reduce risks, and groundwater monitoring indicates no widespread contamination.

## 1.3 Site Status and Contamination Overview

The Mt. Taylor Mine is currently in reclamation status under NMED DP-61 and MMD Permit C1002RE. The site presents dual environmental challenges: legacy radiological contamination from historical uranium mining and localized diesel contamination discovered in 2019 during potable water system rehabilitation. Investigations conducted between 2021 and 2023 delineated a concentrated diesel-impacted zone near the Car Shop and Hoist House, while radiological impacts were identified across broader areas, including the North Controlled Area (NCA), Ore Pad, and several treatment ponds. These findings underscore the need for a unified waste management strategy that consolidates both petroleum-impacted and radiologically elevated soils into a single engineered containment system.

Characterization data indicates that while the primary hotspots for diesel and radionuclides are geographically distinct, there is limited overlap in specific corridors such as the Mine Compound. In the Primary Diesel Release Area, TPH-DRO concentrations range from 4,700 to 11,700 mg/kg, significantly exceeding the NMED industrial soil screening level of 3,000 mg/kg. Radiologically elevated soils often exceed the site-specific investigation level of 6.8 pCi/g for Ra-226. The presence of these adjacent or co-located waste streams necessitates a disposal strategy that leverages the engineered expansion of the on-site disposal cell to prevent localized seepage into the deep-water table, which lies approximately 70 to 95 feet below ground surface. This section establishes the foundation for evaluating whether co-placement is technically and regulatorily appropriate.

# 2.0 SUMMARY OF SITE CHARACTERIZATION DATA

## 2.1 Hydrocarbon Distribution and Concentrations

Hydrocarbons impact at Mt. Taylor Mine are centered on a discrete diesel release discovered in 2019 during potable water system upgrades. Investigations by Ensero Solutions (2021) identified four key borings (MTSB-9, MTSB-10, MTSB-11, and MTSB-14) with Total Petroleum Hydrocarbons in the diesel range (TPH-DRO) far exceeding the NMED industrial Soil Screening Level (SSL) of 3,000 mg/kg (Figure 2.1). Concentrations ranged from 4,700 to 11,700 mg/kg, with the highest values detected between 10 and 15 feet below ground surface. The most severe contamination, estimated at about 7,400 cubic yards, is therefore highly localized and confined to the central operational areas, primarily at substantial subsurface depths. Notably, no free-phase petroleum product was found, and BTEX (benzene, toluene, ethylbenzene, xylenes) concentrations were consistently below regulatory thresholds, indicating that lighter, more mobile diesel fractions have largely dissipated or were never present in significant amounts.

Broader assessment by AVM Environmental Services (2023) extended characterization across the Mine Compound, where diesel odors were detected during radiological surveys. Laboratory results showed that outside the primary release area, diesel concentrations ranged from 22 to 170 mg/kg—well below the actionable 3,000 mg/kg SSL. These low-level impacts are not a regulatory concern and demonstrate that hydrocarbon contamination outside the core release zone is minor, limited, and manageable within the proposed disposal cell. The absence of free product and weathered condition of the diesel further confirm geochemical stability, making the material suitable for excavation and engineered containment. Collectively, the data supports a focused, technically feasible approach for consolidating diesel-impacted soils, minimizing handling complexity and ensuring compliance with state requirements for long-term environmental management.

## 2.2 Radiological and Spatial Overlap Analysis

Radiological surveys across Mt. Taylor Mine have identified significant contamination with Ra-226, uranium isotopes, and gamma anomalies in several key areas, including the North Controlled Area (NCA), Ore Pad, Treatment Ponds, and parts of the Mine Compound. Approximately 23 acres of the NCA, about half of its area, exceed the site-specific investigation threshold of 6.8 pCi/g Ra-226, with particularly deep impacts observed at the Ore Pad and Ore Retention Ponds, where contamination extends to depths of up to 15 feet below ground surface. These findings necessitate engineered containment solutions that comply with EPA 40 CFR 192 and NRC Appendix A, as the radiological impacts are extensive and drive the need for expanding the disposal cell.

Within the Mine Compound, radiological impacts are moderate but still surpass the 6.8 pCi/g threshold in several locations, particularly near the Production Shaft, with contamination reaching depths of about 10 feet. Importantly, these areas also contain low diesel concentrations (≤170 mg/kg), demonstrating that significant overlap between elevated hydrocarbons and radionuclides is minimal. This spatial separation supports the conclusion that a mixed-waste classification is not warranted. The primary contaminants requiring engineered disposal are Ra-226 and uranium, and the presence of low-level diesel in these soils does not change their regulatory status.

A spatial analysis shows that the corridor impacted by diesel (MTSB9 through MTSB14) partially overlaps with radiologically affected soils and the area designated for the expanded disposal cell. In the Mine Compound, soils with elevated Ra-226 to a depth of 10 feet coincide with minor diesel impacts. Table 2.1 summarizes the site areas impacted by diesel and radionuclides. Generally, areas impacted by elevated diesel contamination do not have elevated radionuclide concentrations above the background.

Table 2.1 summarizes how diesel (TPH-DRO) and Ra-226 impacts are distributed across the main Mt. Taylor Mine site areas and highlights why mixed-waste concerns are not triggered. The table shows that the Primary Diesel Release Area contains the only significant diesel exceedances (4,700–11,700 mg/kg, above the 3,000 mg/kg SSL) while Ra-226 remains at background (~1.8 pCi/g), indicating no radiological co-contamination in the diesel hotspot. In contrast, areas such as the North Controlled Area, Ore Pad/Retention Pond, and Treatment Ponds are characterized by elevated Ra-226 (generally above the 6.8 pCi/g investigation level) while diesel is not targeted because it is not a driving concern there. The Mine Compound is the primary area where both constituents are present; however, diesel concentrations are low (≤170 mg/kg) and below the SSL even where Ra-226 exceeds the investigation threshold. Overall, Table 2.1 supports the conclusion that elevated diesel and elevated Ra-226 do not overlap in the same soil mass, supporting co-placement in the engineered disposal cell.

**Table 2.1 Summary of Diesel and Radiological Impacts by Site Area**

| Site Area | Diesel (TPH-DRO) | Radionuclides (Ra-226) | Notable Findings |
|---|---|---|---|
| Primary Diesel Release Area | 4,700–11,700 mg/kg | Background (~1.8 pCi/g) | Significant exceedance of 3,000 mg/kg SSL; no radiological impacts. |
| North Controlled Area (NCA) | Not targeted | >6.8 pCi/g | Approximately 23 acres exceed investigation level. |
| Ore Pad & Retention Pond | Not targeted | Significantly elevated | Radiological impacts extend to ~15 ft bgs. |
| Mine Compound | ≤170 mg/kg | >6.8 pCi/g | Both present, but diesel is low and below SSL. |
| Windblown Area | Not targeted | Localized exceedances | Impacts confined to top ~1 inch. |
| Treatment Ponds (1, 4–8) | Not targeted | >6.8 pCi/g | Radiological impacts in multiple ponds. |
| Marquez Arroyo | Not targeted | Below 6.8 pCi/g | No exceedances. |

# 3.0 REGULATORY CRITERIA AND WASTE CLASSIFICATION

## 3.1 Federal and State Waste Placement Standards

Federal and state regulatory frameworks establish the criteria that govern the placement of diesel-impacted and radiologically elevated soils at the Mt. Taylor Mine. For petroleum-impacted soils, the New Mexico Environment Department (NMED) and the Oil Conservation Division (OCD) provide clear thresholds for total petroleum hydrocarbons (TPH) and associated constituents. The NMED industrial Soil Screening Level (SSL) for diesel-range organics (TPH-DRO) is 3,000 mg/kg, a value exceeded only within the discrete Primary Diesel Release Area. Additional criteria include a benzene limit of 10 mg/kg and a requirement that the upper four feet of reclaimed soil contain less than 100 mg/kg TPH to support vegetation and prevent phytotoxicity. These standards ensure that petroleum-impacted soils placed at depth do not pose risks to human health, ecological receptors, or long-term reclamation performance. The expanded disposal cell design accommodates these requirements by isolating diesel-impacted soils well below the root zone and beneath an engineered cover system.

Federal standards established by the U.S. Environmental Protection Agency (EPA) and the Nuclear Regulatory Commission (NRC) directly regulate radiologically elevated soils. Under EPA 40 CFR 192 and NRC 10 CFR Part 40, Appendix A, site managers must ensure that surface soils do not exceed 5 pCi/g above background and subsurface soils remain below 15 pCi/g above background. Several areas at Mt. Taylor Mine, such as the North Controlled Area, Ore Pad, and former treatment ponds, surpass these thresholds. To address this, the expanded disposal cell uses a low-permeability liner, a radon-attenuating cover, and long-term monitoring provisions that meet or exceed federal performance criteria. Because radiological impacts drive the need for engineered containment, the disposal cell's design specifically supports safe, long-term management of these materials.

The combined regulatory framework allows site managers to co-place diesel-impacted and radiologically elevated soils within the expanded disposal cell. Diesel-impacted soils at Mt. Taylor Mine do not qualify as hazardous waste under RCRA, since they are not listed wastes and lack hazardous characteristics such as ignitability, corrosivity, reactivity, or toxicity. Radiologically elevated soils, while subject to engineered containment, do not overlap with hazardous petroleum impacts in ways that would require mixed-waste classification. Table 3-1 (Summary of Applicable Regulatory Criteria) brings together the main thresholds for TPH, benzene, radium-226, and mixed-waste determinations, confirming that the proposed co-placement approach meets both state and federal requirements. Taken together, these criteria demonstrate that the expanded disposal cell offers an appropriate and compliant solution for managing both waste streams.

## 3.2 Determination of Mixed-Waste Status

A central regulatory question for the Mt. Taylor Mine is whether any soil mass qualifies as "mixed waste," defined under the New Mexico Hazardous Waste Act as material containing both radioactive constituents and RCRA hazardous waste. Diesel-impacted soils at the site do not meet the criteria for hazardous waste under RCRA. They are not listed wastes, and they do not exhibit hazardous characteristics such as ignitability, corrosivity, or reactivity. The toxicity characteristic, evaluated through the Toxicity Characteristic Leaching Procedure (TCLP), is also not triggered.

Although benzene was detected in localized seepage, soil benzene concentrations remain in the micrograms-per-kilogram range, which is orders of magnitude below levels associated with TCLP exceedances. Therefore, diesel-impacted soils are classified as non-hazardous petroleum-impacted soils.

The evaluation further confirms that no area at the site contains both elevated diesel (above 3,000 mg/kg) and elevated radionuclides (above 6.8 pCi/g Ra-226) in the same soil mass. In the Mine Compound, where both contaminants occur, diesel concentrations are low ($\leq$170 mg/kg) and well below regulatory thresholds. Because mixed-waste classification requires simultaneous presence of radioactive material and RCRA hazardous waste, and neither condition is met, the site does not contain mixed waste. This determination significantly simplifies the regulatory pathway for disposal, allowing diesel-impacted and radiologically elevated soils to be co-managed within the expanded disposal cell without invoking dual regulatory oversight.

The applicable regulatory criteria further support this determination. Under NMED petroleum guidance, soils containing TPH-DRO above 3,000 mg/kg require controlled management but are not classified as hazardous waste. Under EPA 40 CFR 192, radiologically elevated soils require engineered containment but are not subject to RCRA unless they also contain hazardous constituents. Because neither the diesel-impacted soils nor the radiologically elevated soils meet the dual criteria required for mixed-waste classification, the site does not contain mixed waste. This conclusion streamlines disposal regulation, permitting co-management of both waste types in the expanded cell under NMED DP-61 and MMD Permit C1002RE, avoiding dual RCRA mixed-waste oversight.

**Table 3.1 Summary of Applicable Regulatory Criteria**

| Regulatory Area | Standard / Threshold | Applicability to Mt. Taylor |
|---|---|---|
| TPH-DRO (NMED/OCD) | 3,000 mg/kg (industrial SSL) | Exceeded only in Primary Diesel Release Area. |
| Benzene (NMED) | 10 mg/kg | Not exceeded in soil; localized seepage only. |
| TPH in top 4 ft (NMED) | 100 mg/kg | Achievable with deep placement in disposal cell. |
| Ra-226 (EPA 40 CFR 192) | 5 pCi/g (surface), 15 pCi/g (subsurface) | Exceeded in NCA, Ore Pad, Treatment Ponds. |
| Mixed Waste (HWA/RCRA) | Must be radioactive + RCRA hazardous | Not triggered; diesel soils are non-hazardous. |

# 4.0 GROUNDWATER AND SEEPAGE CONSIDERATIONS

## 4.1 Hydrogeologic Context and Depth to Water

The hydrogeologic setting of the Mt. Taylor Mine is a critical factor in evaluating the suitability of placing diesel-impacted and radiologically elevated soils within the expanded disposal cell. Groundwater beneath the Mine Compound occurs at depths ranging from approximately 70 to 95 feet below ground surface (bgs), providing a substantial natural buffer between the contaminated soils and the underlying alluvial aquifer. This deep-water table significantly reduces the potential for downward migration of contaminants, particularly when combined with the arid climate and low infiltration rates characteristic of the region. Historical groundwater monitoring data demonstrate that the hydrocarbon contamination identified in 2019 has remained confined to the vadose zone, with no evidence of widespread BTEX or TPH impacts in the groundwater monitoring network.

The low-permeability nature of the underlying bedrock further enhances the natural containment of contaminants. The proposed disposal cell expansion incorporates engineered controls, including a low-permeability liner and a radon-attenuating cover system, are designed to minimize infiltration and prevent leachate generation. These engineered features effectively sever the pathway between surface waste and the subsurface aquifer, ensuring that contaminants remain isolated over the long term. Because the disposal cell will be constructed well above the groundwater table and will include multiple layers of engineered protection, the hydrogeologic conditions strongly support the safe placement of diesel-impacted and radiologically elevated soils within the expanded cell.

## 4.2 Regulatory Significance of Localized Detections

The presence of localized detections of benzene and uranium in seepage samples has important regulatory implications, but these detections do not alter the classification of the soils or trigger mixed-waste criteria. In one borehole (MTSB-10), benzene was detected at 12.2 µg/L, exceeding the New Mexico groundwater standard. However, this detection occurred in seepage, not in a monitoring well, and is interpreted as water that percolated through contaminated soil rather than groundwater from the regional aquifer. Under RCRA, hazardous waste determinations apply to the solid waste itself, not to water that has contacted the waste. Because benzene concentrations in the soils remain far below TCLP toxicity thresholds, the diesel-impacted soils do not meet the definition of hazardous waste.

Localized uranium detections in seepage, such as the measured concentration of 0.817 mg/L at the alluvium-bedrock interface, demonstrate uranium's inherent mobility under specific geochemical conditions; however, these findings do not provide evidence of extensive groundwater contamination. These detections underscore the need for engineered containment but do not change the regulatory status of the soil. Radiologically elevated soils at the site are regulated under EPA 40 CFR 192 and NRC 10 CFR Part 40, Appendix A, which require engineered containment and radon control but do not classify the soils as hazardous waste unless they also contain RCRA-regulated constituents. Because the diesel-impacted soils do not meet hazardous waste criteria, the radiologically elevated soils do not become mixed waste by association.

The regulatory significance of these localized detections lies in their role as indicators of source-area processes, not aquifer-scale impacts. By consolidating diesel-impacted and radiologically elevated soils into a lined and capped disposal cell, RGR effectively addresses the factors responsible for these localized exceedances, specifically by preventing infiltration through unlined, contaminated soils. The expanded disposal cell is specifically designed to prevent such interactions by isolating the waste mass from precipitation, limiting redox cycling, and preventing contact between infiltrating water and contaminated soils. This approach aligns with NMED DP-61 requirements for groundwater protection and supports the conclusion that co-placement is both protective and compliant with applicable regulatory standards.

Table 4.1 consolidates the key groundwater and seepage observations that co-placement is protective and does not change waste classification. The table highlights the deep groundwater table (70–95 ft bgs) as a primary natural protective feature, and notes that BTEX is not detected in monitoring wells, indicating no site-wide hydrocarbon plume. It also documents a localized benzene detection (12.2 µg/L) in MTSB-10 seepage, emphasizing that this is interpreted as seepage from percolation through impacted soil rather than regional groundwater impacts—therefore it does not trigger RCRA hazardous waste status for the soil. Similarly, the table summarizes a localized uranium seepage detection (0.817 mg/L) as evidence of potential mobility under certain conditions, reinforcing the need for engineered containment rather than indicating widespread aquifer contamination. Overall, Table 4.1 supports the rationale that a lined and capped disposal cell will minimize infiltration and leachate potential, thereby addressing the mechanisms that produced these localized detections.

**Table 4.1 Summary of Groundwater and Seepage Findings**

| Parameter | Finding | Regulatory Significance |
|---|---|---|
| Depth to groundwater | 70–95 ft bgs | Provides natural separation from waste; supports safe placement. |
| BTEX in groundwater | Non-detect in monitoring wells | Indicates no widespread hydrocarbon plume. |
| Benzene in MTSB-10 seepage | 12.2 µg/L | Localized seepage; does not trigger hazardous waste classification. |
| Uranium in seepage | 0.817 mg/L | Indicates radiological mobility; supports need for engineered containment. |
| Leachate potential | Negligible under engineered liner | Supports suitability of co-placement in disposal cell. |

# 5.0 TECHNICAL EVALUATION OF CO-PLACEMENT

## 5.1 Physical and Geotechnical Compatibility

The physical characteristics of diesel-impacted and radiologically elevated soils at the Mt. Taylor Mine are sufficiently similar to support co-placement within the expanded disposal cell. Both soil types consist primarily of silty sands and gravels, which are non-plastic, readily compactable, and capable of achieving the density and stability required for engineered waste containment systems. These materials exhibit predictable compaction behavior, allowing them to be placed in controlled lifts that meet the structural requirements of the disposal cell design. The absence of free-phase petroleum product further enhances their suitability, as free product can interfere with compaction, reduce shear strength, and compromise the long-term stability of the waste mass. Because the diesel contamination has weathered, losing its lighter hydrocarbons, the soil acts much like clean granular material when it's excavated and placed.

Operationally, the co-placement of these soils reduces the need for segregated handling, minimizes the active footprint of waste management operations, and streamlines the overall reclamation process. Transporting both waste types to a single engineered containment area reduces equipment movement, lowers the potential for cross-contamination, and simplifies construction sequencing. Because the disposal cell expansion is located within the same operational corridor as the diesel-impacted and radiologically elevated soils, haul distances are short and operational efficiency is maximized. These factors collectively support the conclusion that the physical and geotechnical properties of the soils are compatible with co-placement and will not compromise the structural integrity of the disposal cell.

## 5.2 Geochemical Compatibility and Radionuclide Behavior

Geochemical interactions between diesel-impacted and radiologically elevated soils are not expected to present significant risks when co-placed in the engineered disposal cell. Diesel biodegradation is minimal in the cell’s dry, low-oxygen environment, reducing the likelihood of uranium or radionuclide mobilization. Uranium's mobility increases in oxidizing conditions, particularly with carbonate and dissolved organic carbon, while reducing conditions can either immobilize or remobilize it during redox cycles. Iron and manganese oxides can sorb uranium but release it when reduced (DOE, 2018; Punia et. al., 2021)). The stable geochemical setting limits both hydrocarbon breakdown and radionuclide movement, supporting long-term containment. Diesels do not influence radioactive decay, radon, or gamma emissions. The cell’s cover and liner prevent radon and contaminant migration, maintaining isolation. Together, these controls and natural soil stability confirm that co-placement does not introduce additional geochemical or radiological hazards.

### *5.2.1 Uranium Mobility in the Presence of Hydrocarbons*

The interaction between hydrocarbons and uranium-bearing soils introduces geochemical conditions that can influence uranium mobility within the vadose zone. Hydrocarbons, particularly diesel-range organics, act as electron donors that stimulate microbial activity. As microbes degrade hydrocarbons, they consume oxygen and drive the system toward reducing (low-Eh) conditions. Under these partially reducing conditions, uranium remains in its soluble U(VI) form rather than

converting to insoluble U(IV). Because the reduction process is often incomplete or spatially variable, the resulting redox gradients can enhance uranium mobility rather than immobilize it. These dynamics are especially relevant in semi-arid environments like Mt. Taylor, where infiltration events are episodic and redox conditions can fluctuate rapidly.

Hydrocarbon degradation also produces organic acids, bicarbonate, and dissolved carbon dioxide, all of which promote the formation of soluble uranyl-carbonate complexes. Complexes like $UO_2(CO_3)_2^{2-}$ and $UO_2(CO_3)_3^{4-}$ are very mobile in groundwater and stay stable over a broad range of pH levels. The increased availability of organic ligands and carbonate species enhances uranium solubility and reduces sorption to mineral surfaces. Additionally, slight decreases in pH associated with hydrocarbon biodegradation can dissolve uranium-bearing minerals or destabilize sorption sites on clays and iron oxides, further contributing to uranium mobilization.

Hydrocarbon-driven reduction of iron and manganese oxides can also release uranium previously bound to these mineral phases. As Fe(III) and Mn(IV) oxides dissolve under reducing conditions, sorbed uranium is liberated into porewater. Repeated redox cycling, which often occurs in semi-arid regions during periods of intermittent infiltration, can convert U(IV) back into U(VI), resulting in recurring surges of mobile uranium. These processes underscore the importance of engineered containment systems that minimize infiltration, stabilize redox conditions, and prevent contact between infiltrating water and contaminated soils. The expanded disposal cell design, which incorporates a low-permeability liner, radon-attenuating cover, and moisture-limiting features, effectively mitigates these geochemical mechanisms and ensures long-term isolation of uranium-bearing materials.

### *5.2.2 Hydrocarbon Geochemistry and Implications for Contaminant Behavior*

The geochemical behavior of hydrocarbons in the subsurface plays a central role in determining how diesel-impacted soils interact with radiologically elevated materials. Diesel-range organics (DRO) consist primarily of long-chain alkanes, cycloalkanes, and aromatic hydrocarbons that degrade slowly under the semi-arid climatic conditions present at the Mt. Taylor Mine. In the vadose zone, hydrocarbons undergo limited volatilization and slow microbial degradation due to low moisture availability and restricted oxygen diffusion. As a result, the diesel present at the site is highly weathered, with reduced concentrations of volatile aromatic compounds such as benzene, toluene, ethylbenzene, and xylenes (BTEX). This weathering reduces the potential for hydrocarbon migration and minimizes the likelihood of free-phase product formation, which is consistent with field observations and analytical data showing no measurable free product in any borehole.

Hydrocarbon degradation, although slow, can still influence subsurface geochemistry through the production of organic acids, carbon dioxide, and reduced species. Microbial oxidation of hydrocarbons consumes oxygen and can drive the system toward reducing conditions, particularly in microenvironments where moisture is present. These reducing conditions may promote the dissolution of iron and manganese oxides, which are common sorbents for both hydrocarbons and uranium. The dissolution of these oxides can release previously sorbed contaminants into porewater, although the extent of this process at Mt. Taylor is limited by the site's low moisture content and the weathered nature of the diesel. Additionally, the production of carbon dioxide

during hydrocarbon degradation increases bicarbonate concentrations, which can enhance the formation of uranyl-carbonate complexes and influence uranium mobility.

The physical and chemical properties of diesel-impacted soils also influence their behavior within an engineered disposal environment. Weathered hydrocarbons tend to increase soil hydrophobicity, reducing infiltration and limiting the movement of water through the waste mass. This effect can be beneficial in a disposal cell setting, as it reduces the potential for leachate generation and minimizes contact between infiltrating water and radiologically elevated soils. However, hydrocarbon-impacted soils may also exhibit slightly altered compaction characteristics, depending on moisture content and organic loading. These factors must be considered during waste placement to ensure that compaction specifications are met and that the engineered cover system performs as designed. The expanded disposal cell design accommodates these considerations by requiring controlled lift placement, moisture conditioning where necessary, and verification of compaction through construction quality assurance procedures.

Overall, the geochemical behavior of hydrocarbons at the Mt. Taylor Mine supports the conclusion that diesel-impacted soils are compatible with co-placement in the expanded disposal cell. The hydrocarbons present are weathered, immobile, and geochemically stable under site conditions. Their degradation products, while capable of influencing redox conditions and carbonate chemistry, do so in a manner that is predictable and manageable within the engineered containment system. The combination of natural geochemical stability, limited mobility, and robust engineered controls ensures that hydrocarbon-impacted soils can be safely co-managed with radiologically elevated materials without compromising long-term environmental protection.

### *5.2.3 Combined Contaminant Behavior: Hydrocarbons and Uranium*

The combined presence of hydrocarbons and uranium in the subsurface creates a complex geochemical environment in which the behavior of each contaminant influences the mobility of the other. Hydrocarbons act as electron donors that stimulate microbial activity, consuming oxygen and driving the system toward reducing conditions. These partially reducing conditions can destabilize iron and manganese oxides—key sorbents for uranium—leading to the release of previously immobilized uranium into porewater. At the same time, the degradation of hydrocarbons produces organic acids and bicarbonate, which form strong aqueous complexes with U(VI), enhancing its solubility and mobility. Thus, even though hydrocarbons at the Mt. Taylor Mine are weathered and relatively immobile, their presence can indirectly influence uranium behavior through redox modification and complexation chemistry.

The interaction between hydrocarbons and uranium is further complicated by the semi-arid climatic conditions at the site, which promote episodic infiltration and redox cycling. During wet periods, oxygenated water infiltrates the vadose zone, oxidizing U(IV) to mobile U(VI) and potentially re-mobilizing uranium that had been temporarily immobilized under reducing conditions. During dry periods, microbial degradation of hydrocarbons re-establishes reducing microenvironments, altering the stability of uranium-bearing minerals and sorption sites. These redox oscillations can create repeated pulses of uranium mobility, particularly in zones where hydrocarbons and uranium co-occur at low to moderate concentrations. Although the diesel

hotspot does not overlap with radiological hotspots at Mt. Taylor, the areas where both contaminants occur at low levels may still experience these geochemical interactions.

Despite these potential interactions, the engineered design of the expanded disposal cell effectively mitigates the conditions that promote uranium mobilization in the presence of hydrocarbons. The low-permeability liner and radon-attenuating cover limit infiltration, reducing the likelihood of redox cycling and minimizing contact between infiltrating water and contaminated soils. The engineered cover also maintains stable moisture and oxygen conditions, suppressing microbial activity and slowing hydrocarbon degradation. By isolating the waste mass from climatic fluctuations and controlling the geochemical environment within the cell, the disposal system prevents the formation of conditions that would otherwise enhance uranium mobility. As a result, the combined presence of hydrocarbons and uranium does not pose a long-term risk when managed within the engineered containment system.

**Table 5.1 Hydrocarbon Geochemical Processes Relevant to Uranium Mobility**

| Hydrocarbon Process | Geochemical Mechanism | Effect on Uranium Mobility |
|---|---|---|
| **Microbial degradation of hydrocarbons** | Consumes oxygen, lowers redox potential (Eh) | Maintains uranium in soluble U(VI) form during partial reduction |
| **Production of organic acids** | Generates acetate, lactate, citrate | Forms soluble U-organic complexes; increases mobility |
| **$CO_2$ generation and bicarbonate increase** | Hydrocarbon oxidation produces $CO_2 \rightarrow HCO_3^-$ | Promotes uranyl-carbonate complexes (highly mobile) |
| **Iron and manganese reduction** | Dissolves Fe/Mn oxides | Releases sorbed uranium into porewater |
| **Hydrophobic soil behavior** | Reduced infiltration through hydrocarbon-coated grains | Limits water movement but can create perched microenvironments |
| **pH modification** | Slight acidification from organic acids | Dissolves uranium-bearing minerals; destabilizes sorption |
| **Redox cycling** | Alternating wet/dry conditions | Re-oxidizes U(IV) to mobile U(VI); repeated mobilization pulses |

## 5.3 Hydrocarbon Performance and Liner Integrity

The behavior of diesel within the disposal cell environment is consistent with long-term containment objectives. Under a low-permeability engineered cover, hydrocarbon vapors are negligible, and any residual odors dissipate rapidly once the soils are buried. Research and site-specific evaluations indicate that weathered diesel concentrations at the levels found at Mt. Taylor—up to approximately 1.17% by weight—do not compromise the integrity of high-density polyethylene (HDPE) liners. HDPE is resistant to diesel permeation at concentrations far higher than those present at the site, and the absence of free-phase product further reduces the potential for chemical stress on the liner. This ensures that the liner will maintain its performance over the long-term design life of the disposal cell.

**Table 5.2 Technical Evaluation of Hydrocarbon-Impacted Soil with Radionuclide Waste**

| Impact Category | Technical Consideration | Potential Impact & Integration Issues |
|---|---|---|
| **Geochemical Integration** | **Redox Potential Shifts** | Hydrocarbon degradation consumes oxygen and increases biological activity, which can shift subsurface geochemistry to reducing conditions. This may convert uranium between different oxidation states, potentially altering its stability. |
| **Geochemical Integration** | **Complexation and Solubility** | Organic acids and ligands generated during the biodegradation of diesel can complex with uranium, significantly increasing its solubility and mobility within the cell. |
| **Geochemical Integration** | **Carbonate Equilibria** | Enhanced production of $CO_2$ from hydrocarbon degradation can impact carbonate equilibria, further influencing the mobility of uranium. |
| **Physical Stability** | **Slope and Structural Stability** | Hydrocarbon-impacted soils often exhibit lower shear strength, higher compressibility, and variable moisture content compared to standard mine waste. This can compromise the overall stability of the disposal cell and affect settlement patterns. |
| **Physical Stability** | **Cover System Integrity** | Differential settlement caused by the higher compressibility of oily soils can lead to cracking or failure of the engineered low-permeability cover. |
| **Liner Compatibility** | **Chemical Stress on HDPE** | While weathered diesel at observed concentrations (up to 1.17% by weight) generally does not compromise HDPE, free-phase product or high concentrations could subject the liner to chemical stress or permeation. |
| **Hydrologic Performance** | **Infiltration and Leachate** | Hydrocarbon degradation may alter soil porosity or hydrophobicity. If not tightly compacted, these soils could facilitate moisture pathways that mobilize radionuclides. |
| **Regulatory & Stakeholder** | **Dual Framework Compliance** | Co-placement requires navigating dual standards: NMED Soil Screening Levels for hydrocarbons and NRC/40 CFR 192 for radionuclides. Stakeholders may express concerns regarding the perceived risks of "mixing" these waste streams. |

Tables 5.2 and 5.3 collectively indicate that co-placement is technically achievable, provided that the disposal cell is designed and managed to effectively control key interaction mechanisms. Table 5.2 outlines primary integration risk categories, including geochemical effects (such as redox shifts, organic acid/ligand complexation, and carbonate equilibria that may impact uranium mobility), concerns regarding physical stability (including reduced shear strength, increased compressibility, differential settlement, and potential effects on cover integrity), liner

compatibility (noting that weathered diesel at observed levels typically does not damage HDPE in the absence of free product), hydrologic performance (highlighting the need for sufficient compaction to avoid preferential moisture pathways and leachate production), and regulatory/stakeholder considerations related to managing dual standards within a single unit. Table 5.3 shows that the site's compactable silty sands and gravel are suitable, with no free product detected. Diesel is stable and weathered and does not affect radon or gamma shielding. Furthermore, the HDPE liner and engineered cover are compatible with both waste types, and operational efficiencies support the consolidation of waste into a single engineered unit.

From an engineering perspective, co-placement is the most efficient and technically defensible approach. Segregating diesel-impacted soils from radiologically elevated soils would require the construction of additional disposal units, increasing the long-term stewardship burden without providing measurable environmental benefits. By consolidating both waste streams into a single engineered containment system, RGR can optimize the performance of the radon-attenuating cover, minimize the number of units requiring monitoring, and reduce the overall footprint of waste management infrastructure. This integrated approach aligns with best practices for mine reclamation and long-term environmental stewardship.

To manage environmental and geotechnical risks in the expanded disposal cell, four main engineering controls are advised: maintain low-permeability, oxygen-limited conditions via compaction and moisture; blend hydrocarbon-impacted soil with granular material for stability; use a durable, vegetated cover to reduce infiltration and volatilization; and monitor groundwater for contaminants and settlement. These steps promote consistent waste properties, limit contaminant spread and ensure long-term compliance.

**Table 5.3 Summary of Technical Compatibility Factors**

| Compatibility Area | Findings | Implications for Co-Placement |
|---|---|---|
| Physical properties | Silty sands and gravels; compactable; no free product | Suitable for stable placement in engineered lifts |
| Geochemical behavior | Minimal hydrocarbon degradation; limited redox cycling | Low potential for radionuclide mobilization |
| Radiological performance | Diesel does not affect radon or gamma emissions | Compatible with radon-attenuating cover |
| Liner compatibility | Weathered diesel does not compromise HDPE | Supports long-term containment integrity |
| Operational efficiency | Reduced handling and transport distances | Supports streamlined reclamation |

# 6.0 RISK AND COMPLIANCE EVALUATION

## 6.1 Human Health and Air Pathways

The evaluation of human health risks associated with co-placement of diesel-impacted and radiologically elevated soils focuses on potential exposure pathways during both active construction and long-term post-closure conditions. Once the soils are placed within the expanded disposal cell and covered with the engineered cap, direct exposure pathways—such as incidental ingestion, dermal contact, or inhalation of particulates—are effectively eliminated. The cover system is specifically designed to provide radon attenuation, ensuring that radon flux remains below regulatory thresholds established under EPA 40 CFR 192. Because diesel-impacted soils at the site contain weathered hydrocarbons with negligible vapor pressure, the potential for hydrocarbon vapor emissions is extremely low. This further reduces the likelihood of inhalation risks, even during the active placement phase.

Air pathway risks are also mitigated through standard operational controls during excavation, transport, and placement of the soils. Dust suppression measures, such as water application and controlled equipment movement, minimize the generation of airborne particulates. Air monitoring during construction ensures that worker exposures remain within occupational safety limits. Once the engineered cover is installed, windblown dust is no longer a concern, and the site transitions into a long-term stewardship phase where institutional controls prevent disturbance of the capped waste. Collectively, these measures ensure that co-placement does not introduce unacceptable human health risks and remains consistent with regulatory expectations for mine reclamation and closure.

## 6.2 Groundwater Protection and Long-Term Environmental Risk

Groundwater protection is a central component of the risk evaluation for the expanded disposal cell. Section 4 shows that the deep groundwater table, 70 to 95 feet below ground, acts as a significant natural barrier between waste and the aquifer. The engineered design of the disposal cell further enhances this protection by incorporating a low-permeability liner, drainage layer, and radon-attenuating cover. These features minimize infiltration, prevent leachate generation, and ensure that contaminants remain isolated from groundwater over the long term. The absence of widespread BTEX or TPH detections in the groundwater monitoring network supports the conclusion that hydrocarbon impacts have remained confined to the vadose zone since their discovery.

Long-term environmental risks are further mitigated by the consolidation of diesel-impacted and radiologically elevated soils into a single engineered containment system. This approach reduces the number of potential contaminant sources across the site and eliminates the conditions that contributed to localized seepage exceedances, such as the benzene detection in borehole MTSB-10. By removing impacted soils from unlined areas and placing them in a lined, capped cell, RGR ensures that future infiltration events cannot mobilize contaminants. The long-term monitoring program required under NMED DP-61 and MMD Permit C1002RE provides ongoing verification of groundwater protection, ensuring that any unexpected changes in groundwater quality are promptly identified and addressed.

## 6.3 Regulatory Compliance and Institutional Controls

Compliance with state and federal regulatory requirements is a critical component of the risk evaluation. The co-placement of diesel-impacted and radiologically elevated soils is consistent with the regulatory framework governing both waste types. Diesel-impacted soils at the site do not meet the criteria for RCRA hazardous waste, and radiologically elevated soils require engineered containment regardless of hydrocarbon content. The expanded disposal cell is designed to meet the requirements of EPA 40 CFR 192, NRC Appendix A, and NMED DP-61, ensuring that radon flux, infiltration, and long-term stability criteria are satisfied. Because mixed-waste classification is not triggered, the disposal cell does not require dual regulatory oversight, simplifying compliance and long-term management.

Institutional controls play a key role in ensuring long-term protection of human health and the environment. These controls include land-use restrictions, maintenance of the engineered cover, periodic inspections, and groundwater monitoring. The consolidation of waste into a single engineered unit reduces the number of areas requiring institutional controls and simplifies long-term stewardship. Documentation of waste placement, compaction records, and confirmation sampling results will be maintained to support regulatory review and eventual site release. This integrated compliance framework ensures that the co-placement strategy remains protective, verifiable, and aligned with the long-term reclamation objectives for the Mt. Taylor Mine. Table 6.1 summarizes the risk and compliance factors.

The co-placement strategy meets regulatory requirements and boosts transparency and stakeholder trust. By following clear standards and keeping detailed records, the team shows commitment to environmental and regulatory goals. Regular engagement with agencies and the public builds confidence in the management plan. These actions support approval, site closure, and address concerns about waste streams, ensuring the project aligns with community expectations and best mine reclamation practices.

**Table 6.1 Summary of Risk and Compliance Evaluation**

| Risk Area | Key Findings | Regulatory Implications |
|---|---|---|
| Human health | Exposure pathways eliminated by engineered cover | Meets EPA and NMED health-based standards |
| Air pathways | Negligible hydrocarbons vapor: radon controlled | Complies with 40 CFR 192 radon limits |
| Groundwater | Deep groundwater table; engineered liner prevents leachate | Supports DP-61 groundwater protection |
| Environmental risk | Consolidation reduces contaminant sources | Enhances long-term site stability |
| Regulatory compliance | No mixed-waste criteria triggered | Simplifies permitting and oversight |

# 7.0 DETERMINATION OF SUITABILITY FOR PLACEMENT

## 7.1 Suitability Findings

The comprehensive evaluation of hydrocarbon impacts, radiological conditions, groundwater protection, engineering design, and regulatory criteria demonstrates that diesel-impacted soils containing radiologically elevated materials are suitable for placement within the expanded disposal cell at the Mt. Taylor Mine. The technical analyses confirm that there are no physical, geotechnical, or radiological barriers to co-placement. Diesel-impacted soils exhibit stable physical properties, lack free-phase product, and contain weathered hydrocarbons that do not compromise compaction or liner integrity. Radiologically elevated soils, which represent the primary driver for engineered containment, are already designated for controlled disposal within the expanded cell. The co-location of low-level diesel in some radiological areas does not alter the classification or behavior of the soils and does not introduce new risks.

From a regulatory standpoint, the evaluation confirms that no soil mass at the site meets the dual criteria required for mixed-waste classification under the New Mexico Hazardous Waste Act or RCRA. Diesel-impacted soils are not hazardous waste, and radiologically elevated soils do not coincide with elevated diesel concentrations in a manner that would trigger mixed-waste management. This determination simplifies the regulatory pathway and supports the use of a single engineered containment system. The risk assessment further demonstrates that co-placement reduces long-term environmental risk by removing impacted soils from unlined areas and isolating them within a lined, capped disposal cell designed to meet federal and state performance standards.

## 7.2 Basis of Determination

The determination of suitability is grounded in a multi-disciplinary evaluation that integrates site characterization data, regulatory requirements, engineering design criteria, and long-term environmental protection considerations. Hydrocarbon impacts are limited in extent, well-defined, and geochemically stable. Radiological impacts are more widespread but are already slated for engineered containment. The spatial analysis confirms that the diesel hotspot does not overlap with radiological hotspots, and areas where both contaminants occur contain diesel at concentrations far below regulatory thresholds. This spatial separation is a key factor in determining that mixed-waste criteria are not met and that co-placement is permissible.

Engineering evaluations confirm that the expanded disposal cell is designed to accommodate both waste types without compromising performance. The low-permeability liner, radon-attenuating cover, and infiltration controls ensure that contaminants remain isolated from groundwater and the surrounding environment. The geochemical environment within the cell, which is characterized by low moisture, limited oxygen, and minimal redox cycle, further reduces the potential for hydrocarbon degradation or radionuclide mobilization. Collectively, these findings support the conclusion that co-placement is technically feasible, environmentally protective, and fully compliant with applicable regulatory requirements.

The key determination factors supporting co-placement include: (1) the absence of hazardous waste characteristics in diesel-impacted soils; (2) the spatial separation between diesel hotspots and radiological hotspots; (3) the engineered design of the disposal cell, which meets or exceeds

federal and state performance standards; (4) the deep water table and stable hydrogeologic conditions that limit contaminant mobility; and (5) the regulatory framework, which does not classify the soils as mixed waste. Table 7-1 consolidates these factors and demonstrates that the proposed co-placement approach aligns with all applicable regulatory criteria. Collectively, these findings provide a clear, defensible basis for assessing co-placement is appropriate and protective. Table 7.1 indicates that hydrocarbons contamination is local, weathered, and lacks free product, and radiological contamination is the primary driver for engineered containment and justifies the use of lined, and capped cell. The table highlights that the engineering design (liner and cover) is compatible with both waste types and that groundwater protection is robust due to the deep groundwater table and negligible leachate potential under the engineered system. Finally, Table 7.1 ties these findings to full regulatory compliance (DP-61, C1002RE, and 40 CFR 192), supporting the overall suitability determination.

In addition to the technical and regulatory assessments, ongoing monitoring and adaptive management strategies are proposed to ensure continued compliance and protection of environmental resources. Periodic sampling of groundwater and soil, combined with robust data tracking, will allow for early detection of any unexpected changes in contaminant behavior or migration. The integrated approach also includes contingency protocols for potential remedial actions, should future site conditions warrant intervention. By establishing clear operational guidelines and regular review processes, the placement strategy remains responsive to evolving regulatory standards and scientific advancements. This proactive framework not only reinforces the safety and reliability of the disposal cell but also demonstrates a commitment to transparency and stakeholder engagement throughout the project lifecycle.

**Table 7.1 Summary of Key Determination Factors**

| Evaluation Area | Key Findings | Conclusion |
|---|---|---|
| Hydrocarbon impacts | Localized; weathered; no free product | Suitable for controlled disposal |
| Radiological impacts | Widespread; exceed investigation levels | Require engineered containment |
| Spatial overlap | No overlap of elevated diesel and elevated Ra-226 | Mixed-waste criteria not triggered |
| Engineering design | Liner and cover compatible with both waste types | Supports co-placement |
| Groundwater protection | Deep water table; negligible leachate potential | Protective of aquifer |
| Regulatory compliance | Meets DP-61, C1002RE, 40 CFR 192 | Fully compliant |

# 8.0 IMPLEMENTATION CONDITIONS

## 8.1 Engineering and Operational Requirements for Placement

The successful implementation of co-placement within the expanded disposal cell requires adherence to specific engineering and operational conditions designed to ensure long-term stability and regulatory compliance. First, the disposal cell must incorporate a compliant low-permeability liner system capable of isolating both diesel-impacted and radiologically elevated soils from the surrounding environment. This liner must meet or exceed the performance standards established under NMED DP-61 and EPA 40 CFR 192, including requirements for hydraulic conductivity, thickness, and resistance to chemical degradation. The radon-attenuating cover must be constructed to specifications that ensure long-term control of radon flux, erosion resistance, and moisture infiltration. These engineered components form the foundation of the containment system and must be installed under rigorous quality assurance protocols.

Operationally, the placement of mixed soil must occur in controlled lifts that achieve the compaction standards specified in the engineering design. Proper compaction is essential to maintaining the structural integrity of the waste mass, preventing differential settlement, and ensuring the long-term performance of the cover system. During excavation and transport, soils must be handled in a manner that minimizes dust generation, prevents cross-contamination, and maintains clear separation between waste destined for the disposal cell and materials intended for reuse or reclamation. Equipment operators must follow established haul routes and placement procedures to maintain operational efficiency and environmental protection. These engineering and operational requirements collectively ensure that co-placement is executed safely and in accordance with regulatory expectations.

In addition, robust documentation and verification practices are essential throughout the placement process. Detailed records of liner installation, cover construction, and soil placement must be maintained to demonstrate compliance with regulatory standards and engineering specifications. This includes tracking the source and characteristics of all waste materials, documenting compaction testing results, and recording any corrective actions taken during construction. Regular inspections and third-party quality assurance reviews should be conducted to confirm that all engineered barriers and operational controls are functioning as intended. By maintaining comprehensive documentation and proactive oversight, project stakeholders can ensure that the disposal cell provides reliable containment and meets both environmental and regulatory objectives for the long term.

## 8.2 Confirmation Sampling and Waste Acceptance Criteria

To ensure that only appropriate materials are placed within the expanded disposal cell, confirmation sampling must be conducted during excavation to verify that no free-phase petroleum product is present in the diesel-impacted soils. Free products pose a risk to liner integrity and can compromise compaction, making its exclusion essential. Confirmation sampling should include visual inspection, field screening, and laboratory analysis of representative samples. Analytical parameters should include TPH-DRO, BTEX, and any additional constituents identified during site characterization. Soil exceeding the established waste acceptance criteria must be segregated and evaluated for alternative management options.

Radiologically elevated soils must also be verified through gamma screening and laboratory analysis to ensure that they meet the radiological waste acceptance criteria for the disposal cell. These criteria are based on the design assumptions for radon attenuation and long-term radiological stability. Documentation of all confirmation sampling results must be maintained as part of the project record and made available for regulatory review. This documentation provides assurance that the waste placed in the disposal cell meets the design specifications and regulatory requirements, supporting long-term compliance and environmental protection.

## 8.3 Long-Term Monitoring and Stewardship Requirements

Long-term monitoring is a critical component of the disposal cell's performance and is required under NMED DP-61 and MMD Permit C1002RE. Groundwater monitoring wells located around the disposal cell must be sampled at regular intervals to verify that no leachate is migrating from the waste mass. Analytical parameters should include petroleum hydrocarbons (TPH/BTEX) and radiological constituents (uranium and radium isotopes). Monitoring results must be evaluated for trends, exceedances, and any indications of liner or cover system failure. If anomalies are detected, corrective actions must be implemented promptly to maintain regulatory compliance and protect groundwater resources.

In addition to groundwater monitoring, the physical performance of the disposal cell must be evaluated through periodic inspections of the cover system, drainage features, and erosion controls. Inspections should assess vegetation establishment, settlement, cracking, and stormwater management. Any deficiencies must be addressed through maintenance activities such as regrading, reseeding, or repair of drainage structures. Institutional controls, including land-use restrictions and access limitations, must remain in place to prevent disturbance of the capped waste. These long-term stewardship requirements ensure that the disposal cell continues to function as designed and remains protective of human health and the environment throughout its operational life and beyond.

Table 8.1 presents the critical requirements for the successful co-placement of diesel-impacted soils within the expanded disposal cell, emphasizing both regulatory compliance and long-term stability. These requirements include ensuring containment integrity through verification of the foundation and liner system, such as the installation of a 40-mil HDPE liner and confirmation of an underlying clay layer to prevent contaminant migration. Geochemical control is achieved by maintaining an oxygen-limited, low-permeability environment via appropriate compaction, which reduces the risk of uranium and Ra-226 mobilization. Geotechnical reliability is addressed by strategically blending or layering compressible diesel-impacted soils with granular waste rock to minimize settlement and protect the cover system. Placement depth controls, notably the "5/15 rule," manage material distribution, while a multi-layer engineered cap limits infiltration and volatilization. Fluid management is assured through lined sumps and berms. Verification and stewardship are maintained with confirmation sampling, ongoing groundwater monitoring for TPH/BTEX and radionuclides, regular physical inspections, and enforcement of institutional controls, collectively ensuring the disposal cell's continued protection of human health and the environment.

**Table 8.1 Summary of Key Implementation Requirements**

| Category | Requirement | Technical Objective & Justification |
|---|---|---|
| Foundation & Liner | Liner Integrity & Clay Layer Verification | Ensure the expanded footprint utilizes min. a 40-mil HDPE liner and confirms the presence of an underlying clay liner through test pits to prevent downward migration of contaminants. |
| Geochemical Control | Oxygen-Limited / Low-Permeability Environment | Maintain reducing conditions through high compaction to prevent the mobilization of Uranium and Radium-226. |
| Waste Conditioning | Strategic Blending & Layering | Blend diesel-impacted soils (high compressibility) with dryer, granular waste rock to ensure geotechnical stability and prevent uneven settlement of the cover system. |
| Placement Depth | Subsurface Isolation (The "5/15" Rule) | Place soils with Ra-226 concentrations exceeding 15 pCi/g at depths greater than 15 cm (6 inches) below the final surface to meet federal decommissioning standards. |
| Cover System | Multi-Layer Engineered Cap | Construct a cap with low-permeability layers, erosion-resistant armoring, and vegetative stabilization to minimize infiltration and prevent the volatilization of hydrocarbons. |
| Fluid Management | Lined Sump & Runoff Containment | Install dedicated sump and perimeter berms (e.g., 2-foot interior berms) to collect and evacuate any stockpile runoff or seepage for evaporation. |
| Infrastructure | Source Removal (Piping & Buildings) | Remove, rinse, and dispose of legacy diesel piping within the cell; demolish existing buildings to allow for the full lateral excavation of the hydrocarbon source zone. |
| Verification | Confirmation Sampling (VSP) | Utilize Visual Sample Plan (VSP) software to statistically verify that the floor and sidewalls of the excavation meet the TPH cleanup goal of 3,000 mg/kg. |
| Groundwater monitoring | Regular sampling for TPH/BTEX and radionuclides | Verify containment and detect anomalies |
| Physical inspections | Evaluate cover, drainage, erosion, and settlement | Maintain long-term performance |
| Institutional controls | Land-use restrictions; access limitations | Prevent disturbance of capped waste |

# 9.0 CONCLUSIONS AND RECOMMENDATIONS

## 9.1 Conclusions

The comprehensive evaluation of the Mt. Taylor Mine confirms that co-placement of diesel-impacted and radiologically elevated soils within the expanded on-site disposal cell is appropriate and fully compliant with regulatory standards. Multiple lines of evidence, including detailed contaminant characterization, assessment of hydrogeologic conditions, engineering design review, and adherence to regulatory criteria, support this conclusion. Diesel-impacted soils at the site fall outside the scope of hazardous waste as defined by the RCRA. These soils do not qualify as listed wastes and do not display hazardous characteristics such as ignitability, corrosivity, reactivity, or toxicity. Benzene concentrations in the soil remain well below the thresholds that would trigger TCLP exceedances, and isolated benzene detections in seepage do not affect the overall classification of the solid waste.

Radiologically elevated soils, while requiring engineered containment, do not overlap with areas of elevated diesel in a manner that would necessitate a mixed-waste classification under the New Mexico Hazardous Waste Act. Spatial analysis demonstrates that the diesel-impacted area remains geographically separate from radiological hotspots, and zones where both contaminants are present contain diesel at concentrations well below regulatory thresholds. Because mixed-waste classification requires the simultaneous presence of both radioactive material and RCRA hazardous waste in the same soil mass, and neither condition exists at this site. Thus, the Mt. Taylor Mine does not contain mixed waste. This regulatory finding streamlines the permitting process and authorizes the use of a single, engineered containment system for both waste types.

## 9.2 Recommendations

Based on the technical, regulatory, and environmental analyses provided in this report, it is recommended that Rio Grande Resources (RGR) move forward with co-placing diesel-impacted and radiologically elevated soils within the expanded disposal cell at Mt. Taylor Mine. This strategy offers a comprehensive, efficient, and protective approach to managing legacy site contamination. The engineered disposal cell uses a liner with low permeability, a cover that reduces radon, and thorough long-term monitoring to keep contaminants contained and protect against future exposure risks. Co-placement of these materials into a single containment structure reduces the number of separate waste management units, lessens long-term stewardship demands, and bolsters the stability and sustainability of the reclamation landscape. To ensure proper implementation, RGR should update all permit documentation under NMED DP-61 and MMD Permit C1002RE to clearly authorize the inclusion of non-hazardous petroleum-impacted soils in the radiological cell. Maintaining thorough records—including waste acceptance criteria, confirmation sampling, compaction data, and construction quality assurance—will facilitate regulatory oversight and eventual site closure. Provided RGR adheres to the implementation requirements detailed in Section 8, this integrated approach remains protective, compliant, and consistent with best practices for mine reclamation. There is no technical, regulatory, or risk-based obstacles to this remedy, making it the most practical and effective solution for long-term closure at Mt. Taylor Mine.

Mr. Joe Lister
Rio Grande Resources
P.O. Box 1150
Grants, New Mexico 87020

Dear Mr. Lister,

I'm writing in response to our recent telephone conversation regarding the status of the old drill pads located on Forest Service administered lands on Mt. Taylor. A question had arisen as to whether reclamation of these pads should be done since so much time had elapsed from their creation.

As biologist for the District, my recommendation would be to leave these pads and access roads alone for reclamation purposes. Natural revegetation processes have begun to reclaim these areas. Pads located in ponderosa pine habitat are well grassed and contain seedling trees. Pads and access roads located in pinyon-juniper habitat are less vegetated in the understory, but match the surrounding area. Many have sapling trees that are well started.

While the roads and pads fragment the landscape, which is bad for some species, these leave edge effect habitat which is good for other species. As time passes however, these features are becoming less distinct and will eventually blend into the surrounding area. This is a a desired condition.

Reclamation of the areas at this point would disturb existing vegetation, set the clock back on revegetation already occurring and intensify the edge effect. None of these effects is desirable.

One recommendation could be made. Road density on Mt. Taylor is a significant problem. It is detrimental to all wildlife found there. It would be very beneficial if access roads to drill pads could be blocked. Only those roads presently being driven by vehicles would need to be blocked. Placing large boulders in a defendable place is all that would be needed. Many of these roads are not being used and wouldn't need anything.

Blocking drill pad access roads that are now being driven would also protect revegetation that was taking place or would allow natural establishment of vegetation to occur.

Thank you for the opportunity to comment on this activity. If there should be questions about the recommendations given, please contact me.

| **Re:** | Outfall 001 Historical Summary and Planned Characterization. | | |
| **Cc:** | Kevin Raabe, RGR President<br>Anita Wilcox, MTM Site Supervisor | | |

## 1.0 INTRODUCTION

This technical memorandum summarizes the historical investigations completed at Outfall 001, documents the progression of environmental and radiological investigations conducted to support mine closure, and distinguishes the former discharge pipeline remediation from the Outfall 001 closure activities. Additionally, it describes the planned characterization to support the completion of the Closeout/Closure Plan (CCP). This memorandum provides the technical basis for addressing the New Mexico Environment Department's (NMED) comments regarding Outfall 001 and documents the relationship between previous investigations, completed closure activities, and planned characterization efforts.

## 2.0 BACKGROUND

Historically, treated mine water from the Mt. Taylor Mine was discharged under Discharge Permit DP-61 through a 4.3-mile pipeline terminating at Outfall 001 in San Lucas Canyon. Prior to discharge, mine water was treated to remove radium and other constituents in accordance with permit requirements.

Since the cessation of mine operations, Rio Grande Resources (RGR) has completed multiple investigations to evaluate whether historical treated mine water discharges resulted in impacts to soils, sediments, groundwater, or surface water in the vicinity of Outfall 001 and within the downstream San Lucas drainage. These investigations, conducted between 2013 and 2020, included soil sampling, groundwater monitoring, surface water sampling, sediment characterization, risk evaluation, and radiological surveys completed to support mine closure activities.

The investigations completed between 2013 and 2014 generally concluded that historical treated mine water discharges had not resulted in significant impacts to downstream soils or

groundwater and that no additional characterization was warranted based on the information available at that time (RGR, 2015). As part of subsequent mine closure planning, a radiological gamma survey completed in 2020 identified localized areas of elevated gamma radiation along the former discharge pipeline, including an area at Outfall 001 (RGR, 2020). The survey was conducted as a screening investigation to identify areas requiring additional evaluation during closure planning.

The former treated mine water discharge pipeline was subsequently addressed through the pipeline abandonment project, including remediation of six isolated radiological areas identified along the pipeline corridor and documentation of those activities in the 2025 Final Status Survey (AVM, 2025). While the pipeline abandonment project addressed the designated pipeline corridor removal areas, the Outfall 001 area remained a separate closure feature requiring additional evaluation.

During review of the 2025 CCP, NMED requested clarification regarding the localized elevated gamma radiation identified at Outfall 001 and requested that the CCP either account for any remaining impacted soil requiring disposal or provide documentation demonstrating that reclamation of the Outfall 001 area is complete.

## 3.0 SUMMARY OF HISTORICAL INVESTIGATIONS

The following sections summarize the investigations in chronological order and describe how the technical understanding of Outfall 001 has evolved during mine closure planning.

### 3.1 2013 Outfall Investigation

In 2013, RGR completed a comprehensive investigation of Outfall 001 in response to NMED comments regarding the potential for historical mine water discharges to have impacted soils and groundwater in the vicinity of the outfall (RGR, 2013). The investigation included:

- Surface soil sampling upstream and downstream of the outfall;
- Soil borings and installation of monitoring wells;
- Laboratory analysis of soil uranium concentrations; and
- Groundwater sampling and laboratory analysis.

Based on the analytical results, the investigation concluded that soils near and downstream of Outfall 001 had not been contaminated by historical mine water discharge. Groundwater samples collected from the monitoring wells also did not indicate uranium impacts attributable to historical discharge activities. Based on these findings, no additional investigations were recommended at that time.

### 3.2 2014 Downstream Soil, Surface Water, and Sediment Investigation

Following the 2013 Outfall 001 investigation, RGR conducted additional downstream investigations in 2014 to further evaluate whether historical treated mine water discharges had affected soils, surface water, or sediments within the San Lucas drainage, including the Leopoldo Diversion Dam and Laguna Polvadera impoundments (RGR, 2015). The investigation included

the collection and analysis of surface soil, sediment, and surface water samples from locations downstream of Outfall 001 to evaluate potential concentrations of uranium, selenium, and molybdenum associated with historical mine water discharges (RGR, 2015).

With the exception of one water sample collected from Laguna Polvadera that exceeded the groundwater standard for uranium, analytical results indicated that constituent concentrations in water samples, surface soils and sediments were below NMED's applicable soil screening levels. The investigation further concluded that the Laguna Polvadera impoundment is not used as a drinking water source, is not known to be hydraulically connected to an underlying aquifer and posed no unacceptable risk to human health or ecological receptors. Based on the analytical results, exposure evaluation, and risk assessment, RGR concluded that historical discharges had not resulted in significant downstream impacts requiring additional characterization.

### 3.3 2020 Radiological Survey

In 2020, RGR completed a radiological survey to support mine closure planning and evaluate radiological conditions associated with the former discharge pipeline and Outfall 001 (ERG, 2020). The survey consisted of gamma scans performed along the pipeline corridor and at selected areas, including Outfall 001. Several localized areas of elevated gamma radiation were identified, including an area at Outfall 001. The radiological survey was conducted as a screening investigation to identify areas exhibiting elevated gamma radiation during closure planning. Gamma survey measurements alone do not determine whether soils exceed the Site cleanup criterion of 6.8 pCi/g Ra-226; rather, they identify locations where additional characterization may be appropriate to determine whether remediation is necessary.

### 3.4 2024 Discharge Pipeline Abandonment Work Plan

In 2024, RGR prepared the *Discharge Pipeline Abandonment Work Plan* to support the removal of the former treated mine water discharge pipeline as part of the overall mine closure program (EA, 2024). The Work Plan identified six isolated areas of elevated gamma radiation along the former discharge pipeline that were selected for remediation during pipeline abandonment.

The Work Plan officially recognized that radiological cleanup associated with the pipeline corridor and the evaluation of the Outfall 001 area were separate components of the overall closure program. Accordingly, the proposed pipeline abandonment activities focused on removal of the former discharge pipeline and remediation of the identified pipeline corridor areas, while Outfall 001 remained a separate closure feature requiring additional evaluation.

### 3.5 2025 Pipeline Corridor Radiological Remediation and Final Status Survey

In 2025, RGR completed radiological remediation of the six isolated areas identified along the former treated mine water discharge pipeline and documented the results in the *Final Status Survey – Former Discharge Pipeline Impacted Soil/Limestone Removal Area* (AVM, 2025). Remediation activities included the excavation of impacted soil and limestone material within the identified pipeline corridor removal areas, followed by confirmatory gamma surveys and collection of confirmatory soil sampling to demonstrate compliance with the Site cleanup

criterion of 6.8 pCi/g Ra-226. The Final Status Survey concluded that the remediated pipeline corridor areas satisfied the applicable cleanup criterion and were suitable for unrestricted release.

The Final Status Survey documents remediation and verification activities completed within the designated pipeline corridor removal areas. Characterization and closure of Outfall 001 will be addressed separately as part of the overall mine closure program.

## 4.0 SUMMARY OF FINDINGS

The investigations completed between 2013 and 2025 addressed two complementary aspects of the overall mine closure program: evaluation of potential environmental impacts associated with historical treated mine water discharge and evaluation of localized radiological conditions to support mine closure.

Between 2013 and 2015, investigations evaluated whether historical treated mine water discharges had adversely affected downstream soils, groundwater, surface water, and sediment. Collectively, these investigations concluded that historical treated mine water discharge had not resulted in significant environmental impacts requiring additional characterization based on the information available at that time.

As part of subsequent mine closure planning, the 2020 radiological survey was conducted to identify localized areas of elevated gamma radiation associated with the former treated mine water discharge pipeline and Outfall 001 (ERG, 2020). As a screening investigation, the survey identified areas exhibiting elevated gamma radiation but did not independently determine whether soils exceeded the applicable Site cleanup criterion for Ra-226.

The pipeline abandonment project subsequently addressed the six identified radiological areas along the former discharge pipeline through excavation, confirmation sampling, and Final Status Surveys completed in 2025 (AVM, 2025). Those activities documented completion of remediation within the designated pipeline corridor removal areas but did not document final characterization or closure of the Outfall 001 area.

Collectively, these investigations establish that the environmental investigations evaluating historical treated mine water discharges and the radiological investigations completed to support mine closure represent complementary components of the overall closure program. The historical investigations evaluated potential impacts associated with treated mine water discharge, while the radiological investigations were conducted to support closure by identifying localized areas for additional evaluation. Accordingly, the planned characterization of Outfall 001 represents the next critical step in the closure process and is intended to provide the technical basis for determining whether additional remedial actions are necessary and for documenting final closure of the Outfall 001 area.

## 5.0 PLANNED CHARACTERIZATION

To support completion of the CCP and the final closure of Outfall 001, RGR plans to conduct additional characterization of the Outfall 001 area. The characterization is intended to evaluate

the localized elevated gamma radiation identified during the 2020 radiological screening survey (ERG, 2020) and provide the information necessary to determine whether additional remedial actions are required.

The planned characterization will be designed to:

- Evaluate the area of elevated gamma radiation identified during the 2020 radiological survey;
- Determine whether radionuclide concentrations in soil exceed the applicable Site cleanup criterion;
- Delineate the lateral and vertical extent of any impacted soil, if present;
- Estimate the volume of material requiring excavation and disposal, if necessary; and
- Provide the technical basis for documenting final closure of Outfall 001.

The results of the characterization will be documented in a technical memorandum. Based on the characterization results, a work plan will be prepared, if warranted, describing the proposed remedial approach, estimated material volumes, and confirmation activities necessary to demonstrate compliance with the applicable cleanup criteria.
